# 1 Values

The evaluation of a program, described in section ..., entails among its effects the calculation and manipulation of values.

**FIXME** Draft 1 of the specification does not include a description of evaluation.

An *ECMAScript value* is either undefined, null, or an object. Every ECMAScript value has an associated ECMAScript type, called the value's *allocated type*. The allocated type is fixed when the value is allocated in memory, and cannot change over the lifetime of the value.

#### **Semantics**

**COMPATIBILITY NOTE** In the 3rd edition of the language, several individual *types* were defined. The three types formerly called primitive (number, string, boolean) are now represented as object values. The term *type* has a different meaning in the 4th edition.

## 1.1 Undefined

There is exactly one undefined value, denoted by the semantic value Undefined and stored in the global constant property public..undefined in ECMAScript.

NOTE. The namespace public is predefined and is used for all global names that were also defined by the 2rd Edition Specification.

The allocated type of the undefined value is called the undefined type. The undefined value is the only value with the undefined type as its allocated type. The undefined type is denoted by the semantic value UndefinedType, which is the denoted in ECMAScript type-expression contexts by the identifier undefined.

COMPATIBILITY NOTE: Inside of type expression contexts, the token undefined is reserved and has a fixed meaning. Outside of type expression contexts the token is interpreted as in earlier editions.

#### 1.2 Null

- There is exactly one null value, denoted by the semantic value [Mull] and by the null literal null in ECMAScript.
- The allocated type of the null value is called the null type. The null value is the only value with the null type as its allocated type. The null type is denoted by the semantic value NullType and denoted in ECMAScript type expression contexts by the null literal null.

NOTE While the null and undefined values have similar meanings, they have different conventions of use. The null value is intended to indicate a missing object value, while the undefined value is intended to indicate a missing property on an existing object value. These indeded uses are

# 1.3 Object

- 4 All values except the null and undefined values are object values.
- An object value consists of a mutable property binding map, an immutable object identifier, an immutable tag, and an immutable prototype reference.

#### Semantics

# 1.3.1 Property Binding Map

# 1 Values

1 The evaluation of a program, described in section ..., entails among its effects the calculation and manipulation of values.

**FIXME** Draft 1 of the specification does not include a description of evaluation.

2 An *ECMAScript value* is either undefined, null, or an object. Every ECMAScript value has an associated ECMAScript type, called the value's *allocated type*. The allocated type is fixed when the value is allocated in memory, and cannot change over the lifetime of the value.

#### **Semantics**

**COMPATIBILITY NOTE.** In the 3rd edition of the language, several individual *types* were defined. The three types formerly called primitive (number, string, boolean) are now represented as object values. The term *type* has a different meaning in the 4th edition.

## 1.1 Object Values

- An object value is any ECMAScript value that is not the null value or the undefined value.
- 2 An object value consists of a mutable property binding map, an immutable fixture map, an immutable object identifier, an immutable tag, and an immutable prototype reference.

#### **Semantics**

3 and OBJECT =

```
Object of { propertyMap: PROPERTY MAP, fixtureMap: FIXTURE MAP, ident: OBJECT IDENTIFIER, tag: TAG, proto: VALUE }
```

### 1.1.1 Property Maps

- A property map associates at most one property with any name. If an object's property map associates a property P with a name N, then the object is said to have a binding for N. Alternatively, the property P is said to be bound to the name N, in the object.
- 2 Bindings can be added, removed, or replaced within a property map. The semantic type of a property map is unspecified.
- A property map stores the order in which properties are added to the map. A property's position in this order is unchanged when the property is replaced. This order is used by property enumeration (see the chapter on Statements).

FIXME—"Replacement" is not an adequate abstraction here: we wish to have an "undate" operation. Replacement on the language level occurs when a property is deleted by the delete operator (or an equivalent mechanism) and a new property with the same name is inserted; under this kind of replacement the property's position may change. With a "replacement" on the semantic level, that is to say an undate, the property's position never changes.

#### Semantics

4 and PROPERTY MAP = ...

## 1.1.1.1 Properties

A property consists of a type, a state, and a set of attributes. The type of a property is also called the property's *storage type*, to differentiate it from the allocated type of any value that the property may contain.

**COMPATIBILITY NOTE** In earlier editions of the language, some characteristics of an object were modeled as *internal properties* with distinct names such as <a href="ILValue">ILValue</a>]. These characteristics of objects are described differently in the 4th edition, using a combination of supporting semantic and ECMAScript standard library functionality.

#### Semantics

**FIXME.** The term storage type is not ideal because it also applies to the return value constraint on a function object; there is no "storage" in that context It's possible that annotated type would be a better term.

- A property binding map associates at most one property with any name. If an object's property binding map associates a property  $\mathbb{P}$  with a name  $\mathbb{N}$ , then the object is said to have a *binding* for  $\mathbb{N}$ . Alternatively, the property  $\mathbb{P}$  is said to be *bound to* the name  $\mathbb{N}$ , in the object.
- Bindings can be added, removed, or replaced within a property binding map. The semantic type of a property binding map is unspecified.
- A property binding map stores the order in which properties are added to the map. A property's position in this order is unchanged when the property is replaced. This order is used by property enumeration (see the chapter on Statements).

#### **Comanties**

#### 1.3.1.1 Properties

+ A property consists of a type, a state, and a set of attributes. The type of a property is also called the property's storage type, to differentiate it from the allocated type of any value that the property may contain.

**COMPATIBILITY NOTE** In earlier editions of the language, some characteristics of an object were modeled as *internal properties* with distinct names such as [[Class]] or [[Value]]]. These characteristics of objects are described differently in the 4th edition, using a combination of supporting semantic and ECMAScript standard library functionality.

#### **Semantics**

### 1.3.1.2 Property States

- The *state* of a property encodes either a value associated with the property, or else one of a small number of intermediate non-value conditions that a property can assume during evaluation.
- When a property is created, it is *allocated* in a state that derives from its storage type.
- 3 A property with storage type \* is allocated in the value state, with the undefined value.
- 4 A property with a storage type that has the null type as a subtype is allocated in the value state, with the null value.
- 5 Any other property is allocated in the uninitialized state, and must be initialized during the initialization phase of object construction, before the object's first constructor begins evaluation.
- 6 If a property is in value state, then the allocated type of the value held in the property is a compatible subtype of the storage type of the property.
- 7 Additional property states are defined for encoding non-value properties, such as types, type variables, and virtual properties (defined by getter and setter functions).

#### Comantics

FIXME It is probably not necessary for the getter and setter to be "option", the missing part of the pair is always generated by the language implementation

## 1.3.1.3 Property Attributes

A property can have zero or more attributes from the following set:

Attribute	<b>Description</b>

## 1.1.1.2 Property States

- The state of a property encodes either a value associated with the property, or else a pair of functions that describe a "virtual" value.
- 2 If a property is in the *value* state, reading the property returns the value and writing the property updates the value.
- If a property is in the *virtual value* state, reading the property executes the associated "getter" function, and writing the property executes the associated "setter" function.

#### Semantics

FIXME It is probably not necessary for the getter and setter to be "option", the missing part of the pair is always generated by the language implementation.

## 1.1.1.3 Property Attributes

The attributes of a property govern its behavior in various operations. There are 4 attributes on every property:

Attribute	<b>Description</b>
writable	An attribute that can be one of three values. When the value is Writable, the property can be written to an arbitrary number of times. When the value is WriteOnce, the property can be written to once, after which the attribute assumes the value ReadOnly. When the value is ReadOnly, attempts to write to the property after initialization will fail.
enumerable	A boolean attribute. If true, then the property is to be enumerated by <b>for-in</b> and <b>for-each-in</b> enumeration. If <b>false</b> the property is ignored by such enumeration.
removable	A boolean attribute. If true, then the property can be removed using the <b>delete</b> operator. If false, the <b>delete</b> operator fails.
fixed	A boolean attribute. If true, then the property was defined as a fixture in the object's fixture map and dominates most non-fixed properties during name resolution. If false, then the property is a dynamic addition to the object and is usually consulted <i>after</i> fixed properties during name resolution.

- The fixed attribute is mutually exclusive with the removable attribute.
- 4 If a property is not Writable it is also not removable.
- If a property is fixed it is not enumerable.

## Semantics

6 datatype WRITABILITY = ReadOnly | WriteOnce | Writable

writable	An attribute that can be one of three values. When the value is Writable, the property can be written to an arbitrary number of times. When the value is WriteOnce, the property can be written to once, after which the attribute assumes the value ReadOnly. When the value is ReadOnly, attempts to write to the property after initialization will fail.
enumerable	A boolean attribute. If true, then the property is to be enumerated by <b>for-in</b> and <b>for-each-in</b> enumeration. Otherwise the property is ignored by such enumeration.
removable	A boolean attribute. If true, then the property can be removed using the <b>delete</b> operator. If false, the <b>delete</b> operator fails.
fixed	A boolean attribute. If true, then the property was defined as part of the object's fixed structure and dominates most non-fixed properties during name resolution. If false, then the property is a dynamic addition to the object and is usually consulted <i>after</i> fixed properties during name resolution.

- The fixed attribute is mutually exclusive with the removable attribute.
- 4 If a property is not Writable it is also not removable.
- 5 If a property is fixed it is not enumerable.

#### Semantics

2

← datatype WRITABILITY = ReadOnly | WriteOnce | Writable

# 1.3.2 Object Prototype

The *prototype* of an object is a means of dynamically delegating behavior from one object to another. In various conditions, the language defines the evaluation of an unsuccessful property access on an object in terms of subsequent property accesses on the object's prototype.

# 4.3.3 Object Identifier

The *identifier* of an object uniquely identifies the object. The semantic type of an object identifier is unspecified, and its value cannot be directly observed by ECMAScript code. Equality of objects is partially defined in terms of equality of the objects' identifiers, so all identifiers must be comparable with one another for equality.

#### **Semantics**

and OBJ\_IDENTIFIED -

## 1.3.4 Object Tag

The tag of an object encodes both the object's ECMAScript type, and any underlying semantic value associated with the object.

#### 1.1.1.4 Names

- 1 A name consists of a namespace and an identifier
- 2 A name may identify a property binding within a property map.

#### Semantics

3 type NAME = { ns: NAMESPACE, id: IDENTIFIER }

#### 1.1.1.4.1 Identifiers

1 An *identifier* is a string

#### **Semantics**

2 type IDENTIFIER = STRING

#### 1.1.1.4.2 Names naces

- 1 A namespace is a semantic value that can be either transparent or opaque.
- 2 A transparent namespace consists of a character string that identifies the namespace
- 3 An opaque namespace consists of a unique namespace identifier of unspecified representation.

#### Semantics

4 datatype NAMESPACE =

TransparentNamespace of STRING
OpaqueNamespace of OPAOUE NAMESPACE IDENTIFIER

type OPAOUE NAMESPACE IDENTIFIER = ...

#### Special namespaces

- 5 Two important namespaces are used throughout the following sections.
- 6 The public namespace is the transparent namespace whose identifying string is the empty string.""
- 7 The 4th Edition namespace is the transparent namespace whose identifying string is the string ES4
- 8 All global property names defined subsequently in this specification are written in one of two forms:
  - Qualified\_using the FCMAScript qualified name expression notation namespace::identifier
  - Unqualified, using the notation of a bare identifier, implicitly qualified by the 4th Edition namespace
- The public namespace is bound to the name **nublic**
- 10 More information on special namespaces is given in section... Names. Special namespaces.

## 1.1.2 Object Prototype

- The *prototype* of an object is a means of dynamically delegating behavior from one object to another. In various conditions, the <u>result</u> of an unsuccessful property access on an object <u>is defined</u> in terms of subsequent property accesses on the object's prototype.
- 2 The value of the prototype can be the null value or an object value.

## 1.1.3 Object Identifier

The *identifier* of an object uniquely identifies the object. The semantic type of an object identifier is unspecified, and its value cannot be directly observed by ECMAScript code. Equality of objects is partially defined in terms of equality of the objects' identifiers, so all identifiers must be comparable with one another for equality.

#### Semantics

2 and OBJECT IDENTIFIER = ...

## 1.1.4 Obiect Tag

- 2 The ObjectTag and ArrayTag tags are present on objects of structural types ObjectType and ArrayType, respectively.
- The PrimitiveTag tag is present on objects that are instances of a small number of classes, described in the following section.
- The InstanceTag tag is present on any object that is an instance of a class but does *not* have an ObjectTag, ArrayTag or PrimitiveTag tag.
- The NoTag tag is present only on un-named objects that implement scopes.

#### **Semantics**

```
ObjectTag of FIELD_TYPE list
| ArrayTag of (TYPE list * TYPE option)
| PrimitiveTag of PRIMITIVE
| InstanceTag of CLASS
| NoTag
```

## 1.3.4.1 Primitive Tag

- Some objects have additional an semantic value associated with them. Such objects are called *primitive objects* and have a *primitive tag*. The semantic value is held in the tag, and is only directly accessible in semantic code.
- ECMAScript code can determine if an object is primitive through a correspondence between primitive tags and a set of 10 specific ECMAScript class types. The correspondence is a bijection: any instance of these types has the corresponding primitive tag, and any object with a primitive tag is an instance of the corresponding class.
- The allocated type of a primitive object may be more specific than the corresponding class type. In particular, function objects may have more specific subtypes of the class **public::Function**. In such cases, the allocated type of the object is present in the semantic value held by the primitive tag.
- 4 The correspondence between primitive tags and classes is the following:
  - The primitive tag Poolean corresponds to the class \_\_ES4\_\_..boolean.
  - The primitive tag Double corresponds to the class \_\_ES4\_\_..double.
  - The primitive tag Decimal corresponds to the class \_\_ES4\_\_..decimal.
  - The primitive tag String corresponds to the class \_\_ES4\_\_...string.
  - The primitive tag Namespace corresponds to the class \_\_ES4\_\_..Namespace.
  - The primitive tag Class corresponds to the class \_ES4\_...Class.
  - The primitive tag Interface corresponds to the class \_\_ES4\_\_..Interface.
  - The primitive tag Function corresponds to the class public::Function.
  - The primitive tag Type corresponds to the class \_\_ES4\_\_..Type.
  - The primitive tag Congrator corresponds to the class helper...Generator limpl.

#### **Comunties**

# 5 and DRIMITIVE -

PooleanDrimitive of bool

- + DoubleDrimitive of Peal64 real
- + Decimal Drimitive of Decimal DEC
- + StringDrimitive of Matring STRING
- | NamespaceDrimitive of NAMESDACE
- ClacaDrimitive of CLASS
- InterfaceDrimitive of INTERFACE
- + Function Drimitive of FUN CLOSUPE
- + TypeDrimitive of TVDE
- + Concrator Drimitive of CEN

NOTE The type Real 64 - real represents IEEE 61 bit binary floating point values. The type Decimal . DEC represents IEEE 120 bit decimal floating point numbers. The type Ustring . STRING represents Unicode strings. The type Decimal represents boolean values.

- 1 The tag of an object encodes both the object's allocated type, and any underlying semantic value associated with the object.
- 2 The RecordTag tag is present on an object of with the structural type RecordType as its allocated type.
- 3 The ArrayTag tag is present on an object of with the structural type ArrayType as its allocated type.
- The PrimitiveTag tag is present on objects that are instances of a small number of classes, described in the following section.
- The InstanceTag tag is present on any object that is an instance of a class but does *not* have an **RecordTag**. ArrayTag or PrimitiveTag tag.
- The NoTag tag is present only on un-named objects that implement scopes.

#### **Semantics**

7 and TAG =
 RecordTag of FIELD TYPE list
 ArrayTag of (TYPE list \* TYPE option)
 PrimitiveTag of PRIMITIVE
 InstanceTag of CLASS
 NoTag

#### 1.1.4.1 Primitive Tag

- In addition to an allocated type, some objects have an extra semantic value stored in their tag. Such objects are called *primitive objects* and have a *primitive tag* containing the semantic value. The extra semantic value is only directly accessible in semantic code.
- 2 ECMAScript code can determine if an object is primitive through a correspondence between primitive tags and a set of 2 specific ECMAScript types. The correspondence is a bijection: any instance of these types has the corresponding primitive tag, and any object with a primitive tag is an value of the corresponding type.
- The allocated type of a primitive object may be a subtype of the corresponding type listed here. In particular, function objects may have more specific subtypes of the class **public::Function** and class and interface objects are both subtypes of the interface **helper::Type**. In such cases, the allocated type of the object is described by the semantic value held by the primitive tag.
- 4 The correspondence between primitive tags and object types is the following:
  - The primitive tag BooleanPrimitive corresponds to the class boolean.
  - The primitive tag DoublePrimitive corresponds to the class double.
  - The primitive tag DecimalPrimitive corresponds to the class decimal
  - The primitive tag StringPrimitive corresponds to the class string
  - The primitive tag NamespacePrimitive corresponds to the class Namespace
  - The primitive tag FunctionPrimitive corresponds to the class public::Function
  - The primitive tag TypePrimitive corresponds to the class helper::Type.
  - The primitive tag GeneratorPrimitive corresponds to the class helper::GeneratorImpl.
  - The primitive tag ArgumentsPrimitive corresponds to the class helper::Arguments.

#### **Semantics**

5 and PRIMITIVE =

```
BooleanPrimitive of BOOLEAN

DoublePrimitive of IEEE 754 BINARY 64 BIT

DecimalPrimitive of IEEE 754R DECIMAL 128 BIT

StringPrimitive of STRING

NamespacePrimitive of NAMESPACE

FunctionPrimitive of CLOSURE

TypePrimitive of TYPE

ArgumentsPrimitive of SCOPE

GeneratorPrimitive of GENERATOR
```

### 1.1.5 Fixture Map

A fixture map is a structure that describes but does not contain a set of fixed property bindings. These descriptions of fixed properties are called *fixtures*. The properties described by an object's fixture map are *lazily instantiated* as fixed property bindings on the object. Any attempt to access a property binding described by a fixture in an object's fixture map, but not present in the object's property map, causes the property to be added to the property map.

## 1.4 Semantic Values

Many aspects of the language depend on the semantic values associated with primitive objects. The following sections describe the semantic values and the correspondences that exist between particular semantic values and the ECMAScript values they are held by.

# 1.4.1 Special Constructors

- While much of the behavior of primitive objects is defined *inside* the ECMAScript language (in the section ...library), the means of *constructing* primitive objects and associating semantic values with them is (at least partially) defined *outside* the ECMAScript language, in semantic eode.
- Therefore the construction of any primitive object is described by a *special constructor* defined in semantic <del>code</del>, rather than a *standard constructor* that would otherwise be defined in standard library code. The <del>behavior of each special constructor is described in the following sections.</del>

#### 1.4.2 Boolean Values

A boolean value is either of two semantic values called true and false. These correspond to the ES4 boolean literal values **true** and **false**, which denote the two sole instances of the class <u>ES4\_...boolean</u>. Such objects are called boolean objects.

NOTE The namespace \_E64\_ is predefined. It is used to tag global names that have been introduced in the 4th Edition.

## 1.4.3 Double Values

**FIXME** I cut this section down significantly from ES3, since the corresponding section 8.5 in the old standard mostly consisted of a very weird sort of selective paraphrasing of bits of 754 itself: restatements of algorithms that are perfectly well described in 754, or of facts such as the definition of the denormalized numbers that *never even get used* in the subsequent spec. I assume anyone reading this section and caring about 754 doubles actually has the 754 spec and can read it. Spelling out the whole 754 spec title in this section likewise seems redundant, since that's the point of the normative references section at the beginning of the document.

- + A *double value* is a double precision, 64-bit format binary floating point value, as specified in the IEEE 754 standard.
- A double value can be held in the primitive tag of an instance of the class **\_\_ES4\_\_::double**. Such objects are called *double objects*.
- Two special double values are held in special double objects: one "Not-a-Number" (NaN) value, stored in the global constant **public::NaN**, and one "infinite" value, stored in the global constant **public::Infinity**.

FIXME There are also NaN and Infinity properties (as well as others) on the Number object; those are all double values. ES4 will have NaN and Infinity properties on the docimal object, and probably on the double object for the sake of consistency.

- ECMAScript provides no way of distinguishing any of the different IEEE 754 NaN values from one another. All NaN values in are considered unequal to themselves, and to every other value.
- 5 In this specification, the phrase "the number value of x" where x represents an exact nonzero real mathematical quantity means a number chosen according to the IEEE 754 rounding mode "rounds to nearest".

FIXME That does not take into account decimal.

Some ECMAScript operators deal only with integers in the range -2<sup>31</sup> through 2<sup>31</sup>-1, inclusive, or in the range 0 through 2<sup>32</sup>-1 inclusive. These operators accept any double or decimal value but first convert each such value to one of 2<sup>32</sup> integer values. See descriptions of the ToInt32 and ToUint32 operators in sections ...

## 1.4.4 Decimal Values

- + A decimal value is a 128-bit format decimal floating point value, as specified in the draft IEEE 754r standard.
- A decimal value can be held in the primitive tag of an instance of the class <u>ES4\_::decimal. Such objects are called decimal objects</u>.

2 All instances of a class share a single fixture map.

# 1.2 Undefined Value

- The undefined value is a unique constant denoted by the semantic value <u>UndefinedValue</u> and stored in the global constant property <u>public::undefined</u> in ECMAScript.
- The undefined type is the allocated type of the undefined value. The undefined value is the only value with the undefined type as its allocated type. The undefined type is denoted by the semantic value Undefined Type, which is denoted in ECMAScript type-expression contexts by the identifier undefined.

COMPATIBILITY NOTE. Inside of type-expression contexts, the token undefined is reserved and has a fixed meaning. Outside of type-expression contexts the token is interpreted as in earlier editions.

## 1.3 Null Value

- The null value is a unique constant denoted by the semantic value NullValue and by the null literal null in ECMAScript.
- The null type is the allocated type of the null value. The null value is the only value with the null type as its allocated type. The null type is denoted by the semantic value NullType and denoted in ECMAScript type-expression contexts by the null literal null.

NOTE. While the null and undefined values have similar meanings, they have different conventions of use. The null value is intended to indicate a missing property on an existing object value or an uninitialized property or variable. These intended uses are conventions, and are not enforced by the language semantics.

## 1.4 Semantic Values

Many aspects of the language depend on the semantic values associated with primitive objects. The following sections describe the semantic values and the correspondences that exist between particular semantic values and the ECMAScript values they are held by.

## 1.4.1 Special Constructors

- While much of the behavior of primitive objects is defined *inside* the ECMAScript language (in the section ...library), the means of *constructing* primitive objects and associating semantic values with them is (at least partially) defined *outside* the ECMAScript language, in semantic <u>code and specification prose</u>
- Therefore the construction of any primitive object is described by a *special constructor* defined in semantic code and specification prose, rather than a *standard constructor* that would otherwise be defined in standard library code. The specifications of any such special constructors are given in the following sections, accompanying the specifications of the semantic values.

#### 1.4.2 Boolean Values

- A boolean value is one of two semantic values called true and false. These correspond to the ES4 boolean literal values true and false, which denote the two sole instances of the class boolean. Such objects are called boolean objects.
- 2 No instances of the class boolean can be constructed aside from the two values true and false: the boolean constructor is a special constructor that always evaluates to one of the two boolean objects.

### 1.4.3 Double Values

**FIXME** I cut this section down significantly from ES3, since the corresponding section 8.5 in the old standard mostly consisted of a very weird sort of selective paraphrasing of bits of 754 itself: restatements of algorithms that are perfectly well described in 754, or of facts such as the definition of the denormalized numbers that *never even get used* in the subsequent spec. I assume anyone reading this section and caring about 754 doubles actually has the 754 spec and can read it. Spelling out the whole 754 spec title in this section likewise seems redundant, since that's the point of the normative references section at the beginning of the document.

ETMIE Waldemar objects to that paring down pointing out that the purpose of the selective paraphrasing was to include a specific subset of IEEE 754 arithmetic into ES3. For example, signalling NaNs are not part of that subset, and there are (supposedly) competing round-to-nearest algorithms, of which one needed to be selected. So it's possible that the real fix here is to be explicit as to why a subset of IEEE 754 arithmetic is described in the ECMAScript Specification.

- A double value is a double precision, 64-bit format binary floating point value, as specified in the IEEE 754 standard.
- 2 A double value can be held in the primitive tag of an instance of the class **double** Instances of **double** are called *double* objects.
- Two special double values are held in special double objects: one "Not-a-Number" (NaN) value, stored in the global constant **public::NaN**, and one "infinite" value, stored in the global constant **public::Infinity**.

Some ECMAScript operators convert double values to decimal values when either operand to the operator is a decimal value. This conversion can be lossy.

FIXME More information will appear here.

# 1.4.5 String Values

A string value is a finite ordered sequence of zero or more 32 bit unsigned integer values ("clements"). String values are generally used to represent textual data, in which case each element in the string is treated as a code point value (see section ...). ES3 required code points to be 16 bit unsigned integer values; ES4 will likely allow code points to be either 16 bits or 32 bits.

FIXME This section must accommodate implementations that wish to stick with 16 bit code points, as ES3 requires

- A string value can be held in the primitive tag of an instance of the class **ES4\_::string**. Such objects are called *string objects*.
- Each element of a string is regarded as occupying a position within the sequence. These positions are indexed with nonnegative integers. The first element (if any) is at position 0, the next element (if any) is at position 1, and so on. The length of a string is the number of elements (32-bit values) within it. The empty string has length zero and therefore contains no elements.
- 4 All operations on string (except as otherwise stated) treat them as sequences of undifferentiated 32-bit unsigned integers. In particular, operations on strings do not ensure the resulting string is in normalised form, they do not ensure language-sensitive results, and they do not alter their behavior when dealing with 32-bit values outside the legal range of UTF-32 code points.

**NOTE** The rationale behind these decisions was to keep the implementation of strings as simple and high-performing as possible. The intent is that textual data coming into the execution environment from outside (e.g., user input, text read from a file or received over the network, etc.) be converted to Unicode Normalised Form C before the running program sees it. Usually this would occur at the same time incoming text is converted from its original character encoding to Unicode (and would impose no additional overhead). Since it is recommended that ECMAScript source code be in Normalised Form C, string literals are guaranteed to be normalised (if source text is guaranteed to be normalised), as long as they do not contain any Unicode escape sequences.

**FIXME** The previous paragraphs regarding string values are adapted from ES3, but personally I think they are very awkward-reading, and would like to rewrite them a bit.

- 5 String literals evaluate to string objects.
- The equality of string objects -- in both the == and === sense -- is defined as the equality of the underlying string values. This in turn is established by the identities of the string elements, considered pairwise and in sequence. Inequalities and relational operations of strings are similarly defined in terms of sequence comparisons on string elements. No other forms of textual equality or collation are defined.

## 1.4.6 Namespace Values

4 Namespaces are defined and discussed in section ...names. Their notable features are recounted here.

**TYAME** We should probably define them here and reference this section from the Names chapter.

- 2 A numespace value is either transparent or opaque. A transparent namespace has an associated identifying string value. An opaque namespace has an associated unique identifier of unspecified representation.
- A namespace value can be held in the primitive tag of an instance of the class <u>ES4\_::Namespace</u>. Such objects are called *namespace objects*.
- 4 A namespace value can be defined as a fixture in a global or class static scope using a namespace definition.
- 5 Any two transparent namespaces with equal identifying strings are equal. Any two opaque namespaces with equal identifiers are equal.

#### <del>Ocmantics</del>

6 type ODAQUE NAMESDACE IDENTIFIED -

datatype MAMESDACE =

TransparentNamespace of Ustring STRING

+ OpaquoNamespace of ODAQUE\_NAMESDACE\_IDENTIFIED

FIXME There are also NaN and Infinity properties (as well as others) on the Number object; those are all double values. ES4 will have NaN and Infinity properties on the decimal object and probably on the double object for the sake of consistency.

- 4 ECMAScript provides no way of distinguishing any of the different IEEE 754 NaN values from one another. All NaN values are considered unequal to themselves, and to every other value.
- In this specification, the phrase "the number value of x" where x represents an exact nonzero real mathematical quantity means a number chosen according to the IEEE 754 rounding mode "rounds to nearest".

FIXME That does not take into account decimal.

Some ECMAScript operators deal only with integers in the range -2<sup>31</sup> through 2<sup>31</sup>-1, inclusive, or in the range 0 through 2<sup>32</sup>-1 inclusive. These operators accept any double or decimal value but first convert each such value to one of 2<sup>32</sup> integer values. See descriptions of the ToInt32 and ToUint32 operators in sections ...

## 1.4.4 Decimal Values

- A decimal value is a 128-bit format decimal floating point value, as specified in the IEEE 754r standard.
- 2 A decimal value can be held in the primitive tag of an instance of the class **decimal**. Such objects are called *decimal objects*.
- Some ECMAScript operators convert double values to decimal values when either operand to the operator is a decimal value. This conversion can be lossy.

FIXME More information will appear here.

## 1.4.5 String Values

- A string value is a finite ordered sequence of zero or more unsigned integer values ("elements"). The elements of a string must be either 16 or 32 bits wide. An implementation of ECMAScript may provide elements of either size, but all strings in a single implementation must consist of elements of the same size.
- 2 String values are generally used to represent textual data, in which case each element in the string is treated as a code point value (see section ...).
- A string value can be held in the primitive tag of an instance of the class **string**. Such objects are called *string objects*.
- Each element of a string is regarded as occupying a position within the sequence. These positions are indexed with nonnegative integers. The first element (if any) is at position 0, the next element (if any) is at position 1, and so on. The length of a string is the number of elements (16 or 32-bit values) within it. The empty string has length zero and therefore contains no elements
- All operations on string (except as otherwise stated) treat them as sequences of undifferentiated 16 or 32-bit unsigned integers. In particular, operations on strings do not ensure the resulting string is in normalised form, they do not ensure language-sensitive results, and they do not alter their behavior when dealing with 16 or 32-bit values outside the legal range of UTF-16 or UTF-32 code points, respectively.

NOTE The rationale behind these decisions was to keep the implementation of strings as simple and high-performing as possible. The intent is that textual data coming into the execution environment from outside (e.g., user input, text read from a file or received over the network, etc.) be converted to Unicode Normalised Form C before the running program sees it. Usually this would occur at the same time incoming text is converted from its original character encoding to Unicode (and would impose no additional overhead). Since it is recommended that ECMAScript source code be in Normalised Form C, string literals are guaranteed to be normalised (if source text is guaranteed to be normalised), as long as they do not contain any Unicode escape sequences.

**FIXME** The previous paragraphs regarding string values are adapted from ES3, but personally I think they are very awkward-reading, and would like to rewrite them a bit.

- 6 String literals evaluate to string objects.
- The equality of string objects in both the == and === sense is defined as the equality of the underlying string values. This in turn is established by the identities of the string elements, considered pairwise and in sequence. Inequalities and relational operations of strings are similarly defined in terms of sequence comparisons on string elements. No other forms of textual equality or collation are defined.

### 1.4.6 Namespace Values

- Namespaces are defined in section namespaces
- 2 A namespace can be held in the primitive tag of an instance of the class **Namespace**. Such objects are called *namespace* objects.
- A namespace is defined as a fixture in a global or class static scope by a namespace definition

### 1.4.7 Class Values

- + A class value consists of a name and a set of namespaces, fixtures and types.
- A class value can be held in the primitive tag of an instance of the class \_\_ES4\_\_...Class. Such objects are called class objects.
- A class value can be defined as a fixture in the global scope using a class definition.
- ♣ Each *class definition* corresponds to zero or more class values, and thus zero or more class objects. If a class definition is not type-parametric, it corresponds to exactly one class object, and that class object is called *the value of* the class definition.
- A class value holds class fixtures and instance fixtures. If C is a class object, then the class fixtures of the associated class value describe fixed properties found on the class object C. In this way, the class fixtures effectively describe an implicit anonymous subtype of \_\_ES4\_\_..Class that the class object C is an instance of.

```
FIXME _E94_.. Class is obsolete, probably. It still exists but we have proper metaobjects for this sort of thing.
```

FHAME. This tying-knots staff at the top of the type hierarchy is always a little subtle and hard to word. Suggestions welcome.

6 Class values can be *instantiated* to produce new objects. Instantiation is described in section....

#### Semantics

```
7 and CLASS =
    Class of
    { name: NAME,
        privateNS: NAMESPACE,
        protectedNS: NAMESPACE,
        parentProtectedNSs: NAMESPACE list,
        typeParams: IDENTIFIER list,
        nonnullable: beel,
        dynamic: bool,
        extends: TYDE option,
        implements: TYPE list,
        classRib: RIB,
        instancePib: PIB,
        instanceInits: HEAD,
        constructor: CTOR option,
        classType: TYPE }
```

NOTE ARID datum is a map from property names to fixtures: types, names, and fixture properties

#### 1.4.7.1 Instance Fixtures

- 4 Im addition to class fixtures, a class value holds instance fixtures. These describe the fixed properties found on instances of the class.
- 2 An object is an instance of a class value G if the object's tag is InstanceTag and the class type in the tag is ClassType G.
- If an object X is an instance of a class value C, then for every instance fixture F in C, a property P exists on X satisfying the following conditions:
  - Pis not removable.
  - Pisnot enumerable.
  - Pis fixed.
  - If E is declared as const then the writable attribute of D is initially Writable. Otherwise the attribute is initially Writable.
  - The type of 

    is the type of 

    ...

### 1.4.7.2 Class Types and Class-Instance Types

+ A class corresponds to a pair of types: an instance class type and a static class type.

## 1.4.7 Type Values

- 1 A type value is a description of a set of values. Types are described in chapter—types
- A type value can be held in the tag of an object, in a primitive tag TypePrimitive. An object of such a primitive type tag is called a type object.
- 3 Two sorts of type values are of particular significance; class values and interface values.

#### 1.4.7.1 Class Values

- A class value consists of a name and a set of namespaces, fixture maps types and flags governing the behavior of various objects.
- A class value can be held in a ClassType value, which can be held in the tag of a type object. An object carrying a primitive type tag of class type is called a class object.
- A class value is defined as a fixture in the global scope by a class definition.
- Each class definition corresponds to zero or more class values, and thus zero or more class objects. If a class definition is not type-parametric, it corresponds to exactly one class object, and that class object is called *the value of* the class definition.
- A class value holds class fixtures and instance fixtures. If **C** is a class object, then the class fixture map of the associated class value describes the fixed properties found on the class object **C** and the instance fixture map describes the fixed properties found on objects that are instances of the class value held in **C**.
- 6 If a class definition is type-parametric, each unique application of a set of type arguments produces a new class object with its own property map and unique copy of the class fixture map, specialized to the type arguments provided.
- 2 Class values can be *instantiated* to produce new objects. Instantiation is described in section....

#### **Semantics**

## 1.4.7.2 Instance Types and Class Types

- A class corresponds to a pair of types: an instance class type and a static class type.
- The *instance type* of a class value C is InstanceType C, denoted in a type expression by the name of C itself, and is the allocated type of any instance of C. The tag of any instance of C is InstanceTag C.
- The class type of a class value C is the allocated type of the class object holding C. The tag of such an object is

  PrimitiveTag (TypePrimitive (ClassType C.)). The allocated type of such an object is ClassType C.

  which is defined as a subtype of the InstanceType helper::ClassTypeImpl The class fixtures in the class C are defined as instance fixtures on the class object holding C.

#### 1.4.7.3 Interface Values

- An *interface value* consists of a name and a set of fixtures and types.
- An interface value can be held in an InterfaceType value, which can be held in the tag of a type object. An object carrying a primitive type tag of interface type is called an interface object.
- An interface value is defined as a fixture in the global scope by an interface definition.
- 4 Each *interface definition* corresponds to zero or more interface objects. If an interface definition is not type-parametric, it corresponds to exactly one interface object, and that interface object is called *the value of* the interface definition.

- The instance class type of a class value C is ClassType C, denoted in a type expression by the name of C itself, and is the allocated type of any instance of C. The tag of any instance of C is InstanceTag C.
- The static class type of a class value C is the allocated type of the class object holding C. In such an object, the static class type is stored in a field within C, and is an anonymous subtype of the ClassType of \_\_ES4\_\_...Class. The tag of such an object is PrimitiveTag (Class C).

## 1.4.8 Interface Values

- + An *interface value* consists of a name and a set of fixtures and types.
- 2 An interface <del>closure value can be held in the primitive tag of an instance of the class <u>ES4\_...Interface</u>. Such <del>objects are called interface objects.</del></del>

FHME \_ES4\_...Interface is obsolete, probably. It still exists but we have proper metaobjects for this sort of thing:

- An interface value can be defined as a fixture in the global scope using an interface definition.
- 4 Each *interface definition* corresponds to zero or more interface objects. If an interface definition is not type-parametric, it corresponds to exactly one interface object, and that interface object is called *the value of* the interface definition.
- 5 An interface value contains declarations of *instance fixtures*, but no definitions.
- 6 Interfaces are *implemented* by classes, and any class implementing an interface must define, for each instance fixture declared in the interface, an instance fixture with the same name and type of the instance fixture.
- An interface value I also defines a type InterfaceType I. If a class C implements interface I, the type ClassType C is a subtype of InterfaceType I.

#### **Semantics**

```
8 and INTERFACE =
    Interface of
    { name: NAME,
        typeParams: IDENTIFIER list,
        nonnullable: bool,
        extends: TYPE list,
        ingtangeRib: RIB }
```

### 1.4.9 Function Closures

- A function closure value consists of a captured scope chain, an optional captured this object, and a function value.
- 2 A function closure value can be held in the primitive tag of an instance of the class \_\_\_ES4\_\_\_..Function. Such objects are called *function objects*.
- 3 A function closure value can be defined as a fixture in a scope using a function definition.
- 4 Each function definition corresponds to zero of more function objects.
- 5 A function expression may also evaluate to a function object.
- 6 A function value contains set of parameter fixtures and a block of ECMAScript code.
- 7 Function closure values can be *invoked* to evaluate the ECMAScript code stored in the block of the closure's associated function value. Invocation is described in section....

FIXME Function definitions can be type-parametric; needs to be described.

- 5 An interface value contains declarations of *instance fixtures*, but no definitions.
- 6 Interfaces are *implemented* by classes, and any class implementing an interface must define, for each instance fixture declared in the interface, an instance fixture with the same name and type of the instance fixture.
- An interface value I also defines a type InterfaceType I. If a class C implements interface I, the type ClassType C is a subtype of InterfaceType I.

#### **Semantics**

## 1.4.8 Closure values

- 1 \( \triangle \) closure value consists of a captured scope chain, an optional captured this object, and a function value.
- A closure value can be held in the primitive tag of an instance of the class <u>public:</u> Function. Such objects are called *function objects*.
- 3 A closure value is defined as a fixture in a scope using a **function** definition.
- 4 Each function definition corresponds to zero of more function objects.
- 5 A function expression may also evaluate to a function object.
- 6 A function value contains a set of parameter fixtures, a type, and a block of FCMAScript code.
- 7 Closure values can be *invoked* to evaluate the ECMAScript code stored in the block of the closure's associated function value. Invocation is described in section....

FIXME Function definitions can be type-parametric; needs to be described.

# Reading and Writing Properties

This chapter describes the algorithms for *property access*: testing objects for the presence of a property, reading from and writing to a property, and removing a property. Property access is always by the name of the property. A property name is represented either as an instance of the pre-defined class **Name**, or as a **string** (which represents a name in the **public** namespace).

SPEC NOTE This chapter complements the chapter on names, scopes, and name resolution. At this time, there is some overlap between the two chapters

2 Property accesses are subject to run time checks, and property access fails (an exception is thrown) if a check does not pass. The exact exception depends on the particular check.

NOTE—For example, a property created by let ar const pra property whose type is a non nullable type without a default value must be written (initialized) before it is read; properties created by const cannot be written more than once; and properties that have type annotations can be updated with a new value

```
rund
func
func
func
func

# 2 Reading and Writing Properties

This chapter describes the algorithms for *property access*: testing objects for the presence of a property, reading from and writing to a property, and removing a property. Property access is always by the name of the property. A property name is represented either as an instance of the pre-defined class Name or as a string (which represents a name in the public namespace).

SPEC NOTE This chapter complements the chapter on names, scopes, and name resolution. At this time, there is some overlap between the two

Property accesses are subject to run-time checks, and property access fails (an exception is thrown) if a check does not pass. The exact exception depends on the particular check.

NOTE For example, a property created by Let or const braproperty whose type is a non-nullable type without a default value must be written (initialized) before it is read; properties created by updated with a new value only if the allocated type of the new value is a compatible subtype of the storage type of the property. A ReferenceError is thrown in the first two instances, and a TypeError is thrown in the last.

A property may be virtual, that is to say, the reading and writing of the property may be implemented by *getter* and *setter* methods on the object, and an expression that is syntactically a reference to the property is in fact an invocation of these methods. Virtual dynamic properties may be implemented by *catch-all* methods.

## 2.1 Catch-All Methods

This section contains a normative overview of the catch-all facility. A more precise, also normative, description is given in later sections of this chapter, as part of the general description of property access.

**SPEC NOTE** Any conflicts between the two descriptions are obviously bugs.

- Objects may contain fixture properties in the meta namespace: meta::get, meta::set, meta::has, and meta::delete. These properties always name methods. Jointly they are known as *catch-all methods*.
- If a catch-all method is defined on the object then it is invoked when a dynamic property is accessed: meta::has is invoked to determine if the object has the property; meta::get is invoked to read a property's value; meta::set is invoked to update or create property; and meta::delete is invoked to delete property. A catch-all method is invoked even if the dynamic property that is being accessed already exists on the object.
- 4 A catch-all method operates on the object that contains the method, not on that object's prototype objects.
- 5 If a catch-all method returns normally then the value it returns (if any) becomes the result of the operation, possibly after being converted to a canonical type.
- 6 If a catch-all method throws an exception, and the exception thrown is an instance of the pre-defined class DefaultBehaviorClass, then the default behavior for the catch-all is triggered.

only if the allocated type of the new value is a compatible subtype of the storage type of the property.  $\triangle$  ReferenceError is thrown in the first two instances, and a **TypeError** is thrown in the last.

A property may be virtual, that is to say, the reading and writing of the property may be implemented by *getter* and *setter* methods on the object, and an expression that is syntactically a reference to the property is in fact an invocation of these methods. Virtual dynamic properties may be implemented by *catch-all* methods.

FIXME. We need a definition of "method" this is the first use

#### 2.1 Catch-All Methods

This section contains a normative overview of the catch-all facility. A more precise, also normative, description is given in later sections of this chapter, as part of the general description of property access.

SPEC NOTE Any conflicts between the two descriptions are obviously bugs.

2 Objects may contain fixtures in the **meta** namespace: **meta::get**, **meta::set**, **meta::has**, and **meta::delete**. These properties always name methods. Jointly they are known as *catch-all methods*.

NOTE. The requirement that the meta properties always name methods must be checked by the language implementation. The namespace meta is reserved and known to the implementation and may only be used in specific circumstances. See section ( ).

- If a catch-all method is defined on the object then it is invoked when a dynamic property is accessed: **meta::has** is invoked to determine if the object has the property; **meta::get** is invoked to read the property's value; **meta::set** is invoked to update or create the property; and **meta::delete** is invoked to delete the property. A catch-all method is invoked even if the dynamic property that is being accessed already exists on the object.
- 4 A catch-all method operates on the receiver object of the method call, not on the receiver's prototype objects.
- If a catch-all method returns normally then the value it returns (if any) becomes the result of the <u>property access</u> possibly after being converted to a canonical type.
- **6** If a catch-all method throws an exception, and the exception thrown is an instance of the pre-defined class **DefaultBehaviorClass**, then the default behavior for the catch-all is triggered.
- **DefaultBehaviorClass** is a singleton class; its only instance is is stored in the global constant **DefaultBehavior**.

NOTE The mechanism is analogous to the one defined for iterators, where an instance of the singleton iterator: StopIterationClass is stored in the global property iterator: StopIteration.

- The **meta::get** method is invoked on one argument, a property name. The value returned is the property value. The default behavior for **meta::get** is to retrieve the value from a dynamic property in the object's property map.
- The **meta::set** method is invoked on two arguments, a property name and a value. Any value returned is ignored. The default behavior for **meta::set** is to update or attempt to create a dynamic property in the object's property map.
- The **meta::has** method is invoked on one argument, a property name. Any value returned by the method is converted to **boolean**. The default behavior for **meta::has** is to search for a dynamic property in the object's property map.
- The **meta::delete** method is invoked on one argument, a property name. Any value returned by the method is converted to **boolean**. The default behavior for **meta::delete** is to attempt to delete a dynamic property from the object's property map.

# 2.2 Checking for the Presence of a Property

The HasOwnProperty protocol is invoked to check whether an object *obj* contains a property named by *name*.

**SPEC NOTE** In terms of the 3rd Edition Specification, the **HasOwnProperty** protocol implements the test for whether an object "has a property", as used in the implementations of [[Get11 [[Put11 [[HasProperty]]], and other internal subroutines.

An object is said to contain a property if the property is in the object's property map or if the **meta::has** catchall claims the property to be present.

DefaultBehaviorClass is a singleton class; its only instance is is stored in the global constant DefaultBehavior.

NOTE The mechanism is analogous to the one defined for iterators, where an instance of the singleton StopIterationClass is stored in the global property StopIteration.

- The meta::get method is invoked on one argument, a property name. The value returned is the property value. The default behavior for meta::get is to retrieve the value from a dynamic property in the object's property map.
- The meta::set method is invoked on two arguments, a property name and a value. Any value returned is ignored. The default behavior for meta::set is to update or attempt to create a dynamic property in the object's property map.
- The meta::has method is invoked on one argument, a property name. Any value returned by the method is converted to boolean. The default behavior for meta::has is to search for a dynamic property in the object's property map.
- The meta::delete method is invoked on one argument, a property name. Any value returned by the method is converted to boolean. The default behavior for meta::delete is to attempt to delete a dynamic property from the object's property map.

# 2.2 Checking for the Presence of a Property

The HasOwnProperty protocol is invoked to check whether an object *obj* contains a property named by *name*.

**SPEC NOTE** In terms of the 3rd Edition Specification, the HasOwnProperty protocol implements the test for whether an object "has a property", as used in the implementations of [[Get]],[[Put]],[[HasProperty]], and other internal subroutines.

An object is said to contain a property if the property is in the object's prototype map or if the meta::has catchall claims the property to be present.

```
and hasOwnProperty (regs : REGS)
                    (obj : OBJ)
                          : NAME)
                    (n
    : bool =
    let
                                   meta_has then
            let
                val v = evalNamedMethodCall
                             regs obj meta_has [newName regs n]
            in
                 toBoolean v
            end
            handle ThrowException e =>
                    let
                        val ty = typeOfVal regs e
                        val defaultBehaviorClassTy =
                            instanceType regs FS4_DefaultBehaviorClass []
                        if ty <* defaultBehaviorClassTy then</pre>
                            hasProp props
```

```
true
    else
        if hasFixedProp propertyMap meta_has then
            let
                 val v = evalNamedMethodCall regs obj meta has [newName regs n]
            in
                 toBoolean v
            end
            handle ThrowException e =>
                    let
                        val ty = typeOfVal regs e
                        val defaultBehaviorClassTy =
                            instanceType regs helper_DefaultBehaviorClass []
                    in
                        if ty <* defaultBehaviorClassTy then</pre>
                            hasProp propertyMap n
                        else
                            throwExn e
                    end
            hasProp propertyMap n
end
```

NOTE. The regs parameter represents the virtual machine state. The operator <\* tests subtype compatibility.

# 2.3 Reading a property value

- The <u>GetPropertyValue</u> protocol is invoked to read the value of a property named by *name* from an object *obj*. The flag *isStrict* is true if the ES4 code that caused GetProperty to be invoked was compiled in strict mode.
- 2 Specifically, there will be an AST node for the property reference whose strict flag is set because it represents a source code phrase that was recognized in a region of code that was covered by a strict mode pragma.

**SPEC NOTE** There may be several types of AST nodes carrying strict flags and invoking **GetPropertyValue**, depending on how the AST is eventually structured.

**FIXME** Strict mode is not implemented in this code.

```
and getPropertyValue (regs:REGS)
                        (obj:OBJECT)
                        (name:NAME)
      VALUE =
    getPropertyValueOrVirtual regs obj name true
and getPropertyValueOrVirtual
                                   (regs:REGS)
                                   (obj:OBJECT)
                                   (name:NAME)
                                   (doVirtual:bool)
      VALUE =
    let
         val Object { propertyMap, tag,
         case findProp propertyMap name of
             SOME {state=(ValueProperty v)
             => v
             SOME {state=(VirtualProperty { getter,
              => if doVirtual
                 then
                     case getter of
    SOME g => invokeFuncClosure (withThis regs obj).
                            => UndefinedValue
                      UndefinedValue
            NONE =>
              case Fixture.findFixture (getFixtureMap regs obj) (PropName name) of
                  SOME fixture
                     (reifyFixture regs obj name fixture;
getPropertyValueOrVirtual regs obj name doVirtual)
                  NONE =>
                  case (isNumericName name, tag) of
   (true_ArrayTag ( , SOME defaultType))
                              ArrayTag (
                       => let
                                val defaultVal = defaultValueForType regs defaultType
```

NOTE: The **LOGS** parameter represents the virtual machine state. The operator < \*\* tests subtype compatibility.

# 2.3 Reading a property value

- **+** The GetProperty protocol is invoked to read the value of a property named by *name* from an object *obj*. The flag *isStrict* is true if the ES4 code that caused GetProperty to be invoked was compiled in strict mode.
- Specifically, there will be an AST node for the property reference whose strict flag is set because it represents a source code phrase that was recognized in a region of code that was covered by a strict mode pragma.

**SPEC NOTE** There may be several types of AST nodes carrying strict flags and invoking GetProperty; depending on how the AST is eventually structured

The GetProperty protocol queries the object for the presence of the property using the HasOwnProperty protocol, moving up the object's prototype chain if the object does not contain the property. Once an object on the prototype chain is found that contains the object, the internal getPropertyHolper function is invoked to extract the property value. If no property is found, then a default value may be returned, or, in strict mode, an exception may be thrown.

FIXME. The GetProperty protocol below overlaps with the SearchObject algorithm described in Names, the two algorithms must be reconciled. That will happen when the protocol here is described in terms of 3ML (because then they will use the same code).

#### Semantics

```
4 fun CetProperty(obj, name, isStrict)
    for every object in obj, obj's protetype,
        if HasOwnProperty(obj, name)
        return getPropertyHelper(obj, name, isStrict)
        end
    end
end

if obj allows dynamic property creation

ES4 includes the following types:

## 3.1.1 The any type

The *any type* is the type populated by every possible value. In other words, every other type is a compatible subtype of the any type.

The any type is denoted in a type expression as \*.

No value has the any type as its allocated type. The any type is meaningful only as the storage type of a property.

## 3.1.2 The null type

The *null type* is the type populated only by the <u>semantic value NullValue</u>.

The null type is denoted in a type expression as **null**.

## 3.1.3 The undefined type

The undefined type the type populated only by the semantic value UndefinedValue.

The undefined type is denoted in type expressions as **undefined**.

## 3.1.4 Nominal types

A nominal type is either a class type, an instance type or an interface type.

A class type and an instance type are both defined by a class definition.

An *interface type* is a type defined by an interface definition.

Nominal types are arranged in an explicit subtype relation through the use of **extends** and **implements** clauses in class and interface definitions.

An instance or interface type is denoted in type expressions by the name of the class or interface that defined the type respectively.

6 An instance or interface type C (or C.<T., ..., T.>) can be declared as a non-null type via any of the following declarations:

```
class C! ... X_>! ... interface C! ... interface C.<X,, ... X_>! ...
```

An instance or interface type is *nullable* if it is not a non-null type.

# 3.1.1 The any type

- The *any type* is the type populated by every possible value. In other words, every other type is a compatible subtype of the any type.
- The any type is denoted in a type expression as \*.
- No value has the any type as its allocated type. The any type is only meaningful as the storage type of a property.

# 3.1.2 The null type

- The *null type* is the type populated only by the **null** value.
- The null type is denoted in a type expression as **null**.

## 3.1.3 The undefined type

- The *undefined type* the type populated only by the value stored in the global constant public::undefined.
- The undefined type is denoted in type expressions as **undefined**.

# 3.1.4 Nominal types

- A *nominal type* is either a class type or an interface type.
- A class type is a type defined by a class definition.
- An *interface type* is a type defined by an interface definition.
- Nominal types are arranged in an explicit subtype relation through the use of **extends** and **implements** clauses in class and interface definitions.
- A nominal type is denoted in type expressions by the name of the class or interface that defined the type.

## 3.1.5 Record types

- A record type is a subtype of the **public::Object** class type that has additional type constraints on some specific set of named properties.
- Record types are arranged implicitly into a subtype relation through structural comparison of their property constraints.
- A record type is denoted in a type expression by listing the names of the specified properties in a comma separated list, with optional type annotations, enclosed in curly braces.
- An example is {x: Number, y: String}, which denotes a record type with two properties x and y, the first constrained to type Number and the second to type String. The type {} } denotes the empty record type.

## 3.1.6 Array types

- An *array type* is a subtype of the **public::Array** type that has type constraints on some prefix of the set of all possible integer-indexed properties. An array type may be either *fixed-length* or *variable-length*.
- Array types are arranged implicitly into a subtype relation through structural comparison of their property constraints.

# 3.1.6.1 Fixed-length array types

- † A *fixed-length array type* describes an explicit set of initial integer-indexed property constraints that must be satisfied by properties found at those indices.
- A fixed-length array type is denoted in a type expression by listing the types of the specified properties in a comma-separated list enclosed in square brackets.

# 3.1.5 Record types

- A record type is a subtype of the **public::Object** instance type that has additional type constraints on some specific set of named properties.
- 2 Record types are arranged implicitly into a subtype relation through structural comparison of their property constraints.
- A record type is denoted in a type expression by listing the names of the specified properties in a comma separated list, with optional type annotations, enclosed in curly braces.
- An example is {x: Number, y: String}, which denotes a record type with two properties x and y, the first constrained to type Number and the second to type String. The type { } denotes the empty record type.

# 3.1.6 Array types

- An *array type* is a subtype of the **public::Array** type that has type constraints on some prefix of the set of all possible <u>unsigned-integer-indexed</u> properties. An array type may be either *fixed-length* or *variable-length*.
- 2 Array types are arranged implicitly into a subtype relation through structural comparison of their property constraints.

#### 3.1.6.1 Fixed-length array types

- A fixed-length array type describes an explicit set of initial integer-indexed property constraints that must be satisfied by properties found at those indices.
- 2 A fixed-length array type is denoted in a type expression by listing the types of the specified properties in a comma-separated list enclosed in square brackets.
- For example, the type [Number, String] describes fixed-length arrays of length at least 2, where the entry at index 0 has type Number and the entry at index 1 has type String.
- 4 The type I 1 describes fixed-length arrays of length at least 0, that is, it describes all fixed-length arrays.

FIXME. Do we need to discuss holes here?

#### 3.1.6.2 Variable-length array types

- A variable-length array type describes an explicit set of initial integer-indexed property constraints and then a final constraint that is implied for any further integer-indexed properties (including zero further properties).
- A variable length array type is denoted, initially, the same way a fixed-length array is, but concludes its type list with symbol . . . and a trailing type expression.
- For example, the type [Number, ... String] describes arrays of length at least 1, where the entry at index 0 has type Number, and any remaining entries have type String. The type [ ... Number] describes arrays of zero or more elements, all of which must be of type Number.

## 3.1.7 Union types

- A union type is a storage type that is populated by all values that populate all of the types that make up the union.
- A union type is denoted in a type expresison by listing the types of the union members, separated by the <u>vertical-bar</u> character, enclosed in parentheses.
- For example, the type (Number | String) denotes a type that is populated by both Number and String values. A property annotated with this type can therefore hold either instances of the Number type or instances of the String type.
- 4 No value has a union type as its allocated type. Union types are only meaningful as the storage types of properties.

## 3.1.8 Function types

- A function type is a subtype of the **public::Function** type that describes additional type constraints on any function populating it.
- A function type describes the number and type of required parameters, any optional parameters, any trailing "rest" parameter that accumulates excess arguments, and the return value.
- Function types are denoted with the keyword **function**, followed by a parenthesis-enclosed, comma-separated list of parameter types -- optionally including default and rest symbols -- and an optional colon and trailing return type.

- For example, the type [Number, String] describes fixed-length arrays of length at least 2, where the entry at index 0 has type Number and the entry at index 1 has type String.
- 4 The type 1 describes fixed-length arrays of length at least 0, that is, it describes all fixed-length arrays.

#### 3.1.6.2 Variable-length array types

- A *variable-length array type* describes an explicit set of initial integer-indexed property constraints and then a *final constraint* that is implied for any further integer-indexed properties (including zero further properties).
- A variable length array type is denoted, initially, the same way a fixed-length array is, but concludes its type list with symbol . . . and a trailing type expression.
- For example, the type [Number, ... String] describes arrays of length at least 1, where the entry at index 0 has type Number, and any remaining entries have type String. The type [ ... Number] describes arrays of zero or more elements, all of which must be of type Number.

## 3.1.7 Union types

- + A union type is a storage type that is populated by all values that populate all of the types that make up the union.
- A union type is denoted in a type expresison by listing the types of the union members, separated by the vertical bar character, enclosed in parentheses.
- For example, the type (Number | String) denotes a type that is populated by both Number and String values. A property annotated with this type can therefore hold either instances of the Number type or instances of the String type.
- 4 No value has a union type as its allocated type. Union types are only meaningful as the storage types of properties.

# 3.1.8 Function types

- A function type is a subtype of the **public::Function** type that describes additional type constraints on any function populating it.
- A function type describes the number and type of required parameters, any optional parameters, any trailing "rest" parameter that accumulates excess arguments, and the return value.
- Function types are denoted with the keyword **function**, followed by a parenthesis-enclosed, comma-separated list of parameter types -- optionally including default and rest symbols -- and an optional colon and trailing return type.
- **♣** An example of a function type is:

```
function (Number, String) : String
```

- 5 This function type is populated by any function that is declared as taking a **Number** value and a **String** value as parameters, and returning a **String** value.
- The return type of a function type can be omitted, in which case the return type is implicitly the any type.
- If a function should not return a value, the function return type can be annotated as **void**, which is a notation for defining return types of function types only, there is no separate "void type" that can be denoted elsewhere.
- A function type may include a type constraint for the **this** binding. Such a constraint must be listed as the first parameter in the function type parameter list, and must be denoted with the keyword **this** and a colon. For example, the function type

```
function(this : Number, String) : String
```

denotes a type of functions that require a **Number** value as their implicit **this** parameter, as well as taking a **String** argument and returning a **String**. The type constraint for the **this** binding defaults to the any type \* if omitted.

4 An example of a function type is:

- This function type is populated by any function that is declared as taking a **Number** value and a **String** value as parameters, and returning a **String** value.
- The return type of a function type can be omitted, in which case the return type is implicity the any type.
- If a function should not return a value, the function return type can be annotated as **void**, which is a <u>special notation for indicating the absence of a return type;</u> there is no separate "void type" that can be denoted elsewhere.
- A function type may include a type constraint for the **this** binding. Such a constraint must be listed as the first parameter in the function type parameter list, and must be denoted with the keyword **this** and a colon. For example, the function type

```
function(this: Number, String): String
```

denotes a type of functions that require a **Number** value as their implicit **this** parameter, as well as taking a **String** argument and returning a **String**. The type constraint for the **this** binding defaults to the any type \* if omitted.

A function type may denote the presence of default value assignments for some suffix of its parameter types by annotating the types of such parameters with trailing = symbols. For example, the function type

```
function(Number, String=) : String
```

denotes a type of function that takes a mandatory **Number** argument and an optional second **String** argument, and returns a **String**.

A function type may denote the presence of a trailing "rest-argument" with the symbol . . . in the final position of the function parameter list. This final parameter, if present, indicates that there is no maximum number of arguments to the function: additional arguments beyond the parameter list are collected into an array object and passed to the function. For example, the function type

```
function(String, ...) : String
```

denotes a type of function that takes a **String** and any number of additional arguments (of any type), returning a **String**. Rest arguments cannot have type constraints.

11 Function types can optionally include a parameter name preceding each argument type, and separated from that type by a colon. These parameter names are for documentation purposes only. For example, the type of a substring function might be specified as:

```
function(str : String, start : double, end : double ) : String
```

## 3.1.9 Nullable types

- 1 A *nullable type* is an abbreviation for a union between some type and the null type.
- 2 A nullable type is denoted **?T** for some type **T**.
- 3 For example, the nullable type ?String is an abbreviation for the union type (String | null).
- 4 Nullable types are purely a syntactic convenience, and are not given further special treatment.

#### 3.1.10 Non-null types

- A non-null type is a type that excludes the **null** value from the population of a nullable <u>instance</u> or interface type.
- A non-null type is denoted ! **T** for some <u>instance</u> or interface type **T**.
- For example, the non-null type !String is populated by instances of public::String but excludes null values.

## 3.1.11 Parametric types

- A parametric type is a user-defined type constructor -- not a proper type -- associated with some type definition such as an instance type interface type or type abbreviation. A parametric type takes some number of types as arguments and produces a new type as its result.
- Parametric types are denoted by appending a type-parameter list to the name of a class, interface, or type at the site of its definition. A type parameter list consists of a single period, a less-than (or "left angle bracket") character, a comma-separated list of identifiers, and a greater-than (or "right angle-bracket") character.

A function type may denote the presence of default value assignments for some suffix of its parameter types by annotating the types of such parameters with trailing = symbols. For example, the function type

```
function(Number, String=) : String
```

denotes a type of function that takes a mandatory **Number** argument and an optional second **String** argument, and returns a **String**.

A function type may denote the presence of a trailing "rest-argument" with the symbol . . . in the final position of the function parameter list. This final parameter, if present, indicates that there is no maximum number of arguments to the function: additional arguments beyond the parameter list are collected into an array object and passed to the function. For example, the function type

```
function(String, ...) : String
```

denotes a type of function that takes a **String** and any number of additional arguments (of any type), returning a **String**. Rest arguments cannot have type constraints.

Function types can optionally include a parameter name preceding each argument types, and separated from that type by a colon. These parameter names are for documentation purposes only. For example, the type of a substring function might be specified as:

```
function(str : String, start : double, end : double ) : String
```

# 3.1.9 Nullable types

- + A *nullable type* is an abbreviation for a union between some type and the null type.
- A nullable type is denoted ?T for some type T.
- For example, the nullable type ?String is an abbreviation for the union type (String | null).
- Nullable types are purely a syntactic convenience, and are not given further special treatment.

## 3.1.10 Non-null types

FIXME: Cormac recently reformulated the non-null operator such that it does "not" model deletion of null-from union but rather persists, as a normal-form of a type term, wrapping a class or interface type, and modifies the contained class or interface type to reject null as a subtype. It works this way too, but there may be left over text that describes it the older way.

- A non-null type is a type that excludes the **null** value from the population of a nullable chass or interface type.
- A non-null type is denoted ! T for some class or interface type T.
- For example, the non-null type !String is populated by instances of public::String but excludes null values.

## 3.1.11 Parametric types

- A parametric type is a user-defined type constructor -- not a proper type -- associated with some fixed definition such as a class, interface or type definition. A parametric type takes some number of types as arguments and produces a new type as its result.
- 2 Parametric types are denoted by appending a type-parameter list to the name of a class, interface, or type at the site of its definition. A type parameter list consists of a single period, a less-than (or "left angle bracket") character, a comma-separated list of identifiers, and a greater-than (or "right angle-bracket") character.
- 3 For example, the class definition

```
class Vector.<X> { .. }
```

defines a class **Vector** that is parameterized over a single type variable **X**. This class therefore also serves as a parametric type that can be used in type applications to form proper types.

# 3.1.12 Type applications

3 For example, the class definition

```
class Vector.<X> { .. }
```

defines a class **Vector** that is parameterized over a single type variable **x**. This class <u>definition</u> itherefore also serves as a <u>parametric instance</u> type that can be used in type applications to form proper types.

## 3.1.12 Type applications

- A type upplication is a combination of a parametric type with a set of type arguments that serve to instantiate the parametric type into a proper type that can be populated by values.
- A type application is denoted by appending a type argument list to the name of a parametric type. A type argument list consists of a single period, a less-than character, a comma-separated list of type expressions, and a greater-than character.
- For example, the type application **Vector.<Number>** denotes an instance type that can be used as the allocated type of new objects.

# 3.1.13 Type names

- 1 A type pame is a symbolic reference to an instance type, an interface type, a type abbreviation, or a type variable bound by a parameter in a parametric type.
- A type name is denoted in a type expression by the same syntax as a name expression
- 3 Type names are resolved during *type resolution*, described in Section 3.3 below.

# 3.2 Semantics of the Type Language

```
Semantics
and TYPE =
      AnyType
NullType
     UndefinedType
     RecordType of (NAME EXPRESSION * TYPE) list
ArrayType of (TYPE list * TYPE option)
      UnionType of TYPE list
      FunctionType of FUNCTION TYPE
     NonNullType of TYPE
AppType of (TYPE * TYPE list)
TypeName of (NAME_EXPRESSION * NONCE option)
     ClassType of CLASS
InstanceType of CLASS
InterfaceType of INTERFACE
and FUNCTION TYPE =
        typeParams : IDENTIFIER list,
thisType : TYPE,
params : TYPE list,
         params:
         minArqs: int,
nasRest: BOOLEAN
result: TYPE op
                                               (* NONE indicates return type is void *)
                       TYPE option
type NONCE = int
To help avoid name collisions, each type variable bound in a type parameter list is assigned a unique integer, or nonce. Any
reference to that type variable is then resolved into a TypeName that includes that nonce
          Type Resolution
At run-time, when a type is encountered in the source program, that type is immediately resolved. This type resolution
process proceeds as follows
In the scope of a type definition
      type X = S
any reference to a type variable \mathbf{x} in \mathbf{x} is replaced by the type \mathbf{s}.
```

In the scope of a parametric type definition

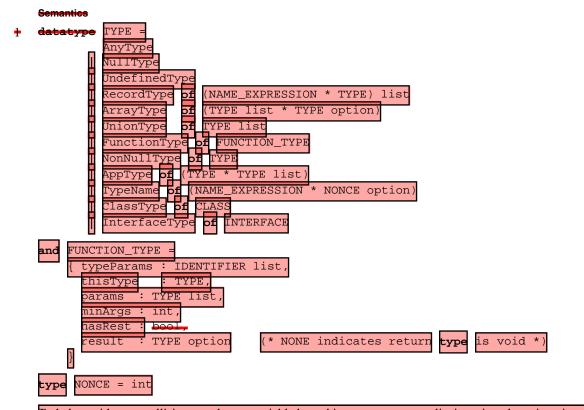

- A type application is a combination of a parametric type with a set of type arguments that serve to instantiate the parametric type into a proper type that can be populated by values.
- A type application is denoted by appending a type-argument list to the name of a parametric type. A type argument list consists of a single period, a less-than character, a comma-separated list of type expressions, and a greater-than character.
- For example, the type application type of new objects.

  Vector. < Number > denotes an elass type that can be used as the allocated type of new objects.

# 3.1.13 Type names

- A *type name* is a symbolic reference to a class, an interface, a type definition, or a type variable bound by a parameter in a parametric type.
- A type name is denoted in a type expression by the same syntax as a name expression.
- 3 A type name that refers to a class resolves to a class type. A type name that refers to an interface resolves to an interface type.

# 3.2 Semanties of the Type Language

To help avoid name collisions, each type variable bound in a type parameter list is assigned a unique integer, or nonce. Any reference to that type variable is then resolved into a TypeName that includes that nonce.

# 3.3 The Subtype and Type Equivalence Relations

## 3.3.1 The Subtype Relation

- **†** The *subtype relation* is a binary relation on types. It is defined by the collection of subtype rules described below and in the following subsections.
- Subtyping is reflexive, so every type is a subtype of itself.
- Subtyping is transitive, so if **S** is a subtype of **T** and **T** is in turn a subtype of **U**, then **S** is also a subtype of **U**.

## 3.3.2 Implementation of the Subtype Relation

```
type K \cdot \langle y_1, \dots, y_n \rangle = S
                                              S_n > [n] is replaced by the type S[y_1 := S_1, \dots, y_n := S_n]
a type application
 <del>n the scope<sub>l</sub>of a class definition that associat</del>es a non-nullable instance type name 🖥 with a class definition D, type resolution
 replaces any TypeName that refers to with InstanceType D. For references to a nullable instance type, the same
                     is made, but the result (or the enclosing AppType node, if there is one) is unioned with the null type.
 Similarly, in the scope of an interface definition that associates an interface name with an interface definition D, type esolution replaces any TypeName that refers to with InterfaceType D (again, unioned with the null type, in the control of th
                                                                                                                              D (again, unioned with the null type, if
nullable interface).
                  Implementation of Type Resolution
3.3.1
The following function resolveTypeNames performs type resolution on a particular type by
                                                                                                                                                               in the context of an
environment env
This function relies on the auxiliary function Fixture.resolveNameExpr (described in section ...) to resolve each type
name. The function Fixture resolven ameExpr finds the corresponding fixture, and returns a triple contenuing environment that fixture was defined in: (2) the fully-resolved name for the given name expression, and (3) the
corresponding fixture.
If the resulting fixture is for a non-parametric type definition, the body of that type definition is resolved in its environment
and then replaces the original type name.
If the resulting fixture is for a class or interface definition, the type name is replaced by an instance type or an interface type
(unioned with the type null if the instance or interface type is declared as nullable).
A type application that refers to a type parametric type definition is replaced by the body of that type definition, after the
replacement of each formal parameter name with the corresponding resolved type argument.
A type application of a type name that refers to a type-parametric instance type or interface type is replaced by a type
application that directly includes that instance or interface type (unioned with the type null if the nominal type is declared
as nullable).
f none of the above cases apply, then resolve Type Names uses the helper function map Type to perform type name
resolution on each sub-term of the given type
The function error reports error messages, and the module LogErr contains functions for converting various data structures into corresponding Strings.
Semantics

                                                  ClassFixture (c as Class
                                                                                                            {nonnullable
                                                                                                                                            typeParams=[]
                                     maybeUnionWithNull nonnullable (InstanceType c)
                                    InterfaceFixture (i as Interface {nonnullable, typeParams=[], ...})) =>
maybeUnionWithNull nonnullable (InterfaceType i)
```

- The subtype relation is defined by the following function subType. This function takes an additional argument called extra, which is later used to extend the subtype relation with additional rules (for example, to define the compatible subtyping relation below).
- 2 Reflexivity is included explicitly in the code below, whereas transitivity is a consequence of the remainder of the algorithm. This function dispatches to additional subtype functions described in the following subsections.

#### Semantics

# 3.3.3 The Type Equivalence Relation

The type equivalence relation is also a binary relation on types. Two types are equivalent if and only if they are both subtypes of each other.

### 3.3.3.4 Implementation of the Type Equivalence Relation

The function equivType below checks type equivalence in a straightforward manner by checking subtyping in both directions. Like subType, equivType also takes an extra parameter.

**EMPLEMENTATIONNOTE** The following implementation is straightforward and sufficies for a specification, but its worst-case time complexity is exponential in the height of a type, and so this naive approach would be inadequate in an implementation.

#### Semantics

# 3.3.4 Subtyping Record Types

- 1 A record type  $\{N_1:S_1, \ldots, N_n:S_n\}$  (where each distinct  $N_i$  is a name and each  $S_i$  is a type) is a subtype of  $\{N_1:T_1, \ldots, N_m:T_m\}$  if  $m \le n$  and  $S_i$  is equivalent to  $T_i$  for all i in 1..m.
- The ordering of the **Name: Type** bindings in a record type is irrelevant, and so re-arranging these bindings yields an equivalent type. In particular, this re-arranging may be necessary in order to make the above rule applicable. The function nameExpressionEqual checks if two field names are equal.

```
and subTypeRecord extra type1 type2 =
    case (type1, type2) of

(RecordType fields1, RecordType fields2) =>
    List.all (fn ( name1, type1 ) =>
    List.exists (fn ( name2, type2 ) =>
    nameExpressionEqual name1 name2 andalse
```

```
(_, n, _) => error ["name ", LogEr LogErr.ty ty,

          Resolved Types
A resolved type is one that is the result of the preceding type resolution process.
Resolved types do not include:
       ype names that refer to instance or interface types (InstanceType and InterfaceType are used instead)
        ype names that refer to type abbreviations (which are inlined)
Resolved types may include type names that refer to type parameters; these references include a nonce.

# 3.3.5 Subtyping Array Types

- + A fixed-length array type [S<sub>1</sub>, ..., S<sub>n</sub>, S] is a subtype of [S<sub>1</sub>, ..., S<sub>n</sub>]. The supertype demands one fewer element in the array than the subtype does. For example, [Number, String, String] is a subtype of [Number, String].
- A fixed-length array type  $[S_1, ..., S_n]$  is a subtype of  $[T_1, ..., T_n]$  if each  $S_i$  is equivalent to  $T_i$  for i in 1..n.
- A variable-length array type [S<sub>1</sub>, ..., S<sub>n</sub>, S, ... S] is a subtype of [S<sub>1</sub>, ..., S<sub>n</sub>, ... S]. The supertype demands one fewer element in the array than the subtype does. For example, [Number, String, String, ... String] is a subtype of [Number, ... String], via transitivity.

NOTE Since . . . denotes concrete syntax, we use the *meta-syntax*  $S_1$ , . . . ,  $S_n$  to denote a sequence of zero-or-more communication types.

- A variable-length array type  $[S_1, \ldots, S_n, \ldots, S]$  is a subtype of  $[T_1, \ldots, T_n, \ldots, T]$  if S is equivalent to T and if each  $S_i$  is equivalent to  $T_i$  for i in 1..n.
- 5 Via transitivity, the above rules may be applied multiple times, in various combinations. The following code combines all of these rules into a single deterministic algorithm for array subtyping.

#### Semantics

```
and subTypeArray extra type1 type2 =
    case (type1, type2) of
        (ArrayType (types1, rest1),
         ArrayType (types2, rest2))
        let
            val min = Int.min( length types1, length types2 )
        in
            ListPair.all (fn (type1, type2) => equivType extra type1 type2)
                         (List.take(types1, min),
                          List.take(types2, min))
            andalso
            (case (rest1, rest2) of
                 (NONE,
                          NONE
                                 ) => length types1 >= length types2
               (NONE,
                           SOME _ ) => false
               | (SOME _, NONE ) => false
               | (SOME t1, SOME t2) =>
                 length types1 >= length types2 andalso
                 equivType extra t1 t2 andalso
                 List.all (fn types1 => equivType extra type1 t2)
                          (List.drop(types1, length types2)))
        end
      | _ => false
```

## 3.3.6 Subtyping Union Types

- The *subtype relation* is a binary relation on types. It is defined by the collection of subtype rules described below and in the following subsections.
- 2 Subtyping is reflexive, so every type is a subtype of itself.
- Subtyping is transitive, so if  $\bf{S}$  is a subtype of  $\bf{T}$  and  $\bf{T}$  is in turn a subtype of  $\bf{U}$ , then  $\bf{S}$  is also a subtype of  $\bf{U}$ .

# 3.4.2 Implementation of the Subtype Relation

- The subtype relation is defined by the following function subType. This function takes an additional argument called extra, which is later used to extend the subtype relation with additional rules (for example, to define the compatible subtyping relation below).
- 2 Reflexivity is included explicitly in the code below, whereas transitivity is a consequence of the remainder of the algorithm. This function dispatches to additional subtype functions described in the following subsections.

#### Semantics

## 3.4.3 The Type Equivalence Relation

The type *equivalencel* relation is also a binary relation on types. Two types are equivalent if and only if they are both subtypes of each other.

### 3.4.3.1 Implementation of the Type Equivalence Relation

The function equivType below checks type equivalence in a straightforward manner by checking subtyping in both directions. Like subType, equivType also takes an extra parameter.

**IMPLEMENTATION NOTE** The following implementation is straightforward and sufficies for a specification, but its worst-case time complexity is exponential in the height of a type, and so this naive approach would be inadequate in an implementation.

#### Semantics

### 3.4.4 Subtyping Record Types

- A record type  $\{N_1: S_1, \ldots, N_n: S_n\}$  (where each distinct  $N_i$  is a name and each  $S_i$  is a type) is a subtype of  $\{N_1: T_1, \ldots, N_m: T_m\}$  if  $m \le n$  and  $S_i$  is equivalent to  $T_i$  for all i in 1...m.
- The ordering of the **Name: Type** bindings in a record type is irrelevant, and so re-arranging these bindings yields an equivalent type. In particular, this re-arranging may be necessary in order to make the above rule applicable. The function nameExpressionEqual checks if two field names are equal.

```
Semantics
```

- A union type  $(S_1 \mid ... \mid S_n)$  is a subtype of a type **T** if  $S_i$  is a subtype of **T** for all i in 1...n.
- 2 A type **S** is a subtype of  $(\mathbf{T}_1 \mid ... \mid \mathbf{T}_n)$  if there exists some i in 1... such that **S** is a subtype of  $\mathbf{T}_1$

#### **Semantics**

```
and subTypeUnion extra type1 type2 =
    case (type1, type2) of

          (UnionType types1, type2)
          => List.all (fn type1 => subType extra type1 type2) types1

| (type1, UnionType types2)
          => List.exists (fn type2 => subType extra type1 type2) types2

+ = > false
```

# 3.3.7 Subtyping Function Types

+ A function type  $function(S_1, ..., S_n)$ : U is a subtype of  $function(T_1, ..., T_n)$ : T is equivalent to T for all i in 1..m.

NOTE Function subtyping is invariant in the argument position, and covariant in the result type.

This rule generalizes to **this** arguments, default arguments, and rest arguments according to the following rule, where the number of default arguments (indicated via the = symbol) in each function type may be zero, and where [...] indicates an optional rest argument. A function type

```
function(this:S_1, S_2, ..., S_n, S_{n+1} = , ..., S_m = , [...]) : U
```

is a subtype of

function(this:
$$T_1$$
,  $T_2$ , ...,  $T_p$ ,  $T_{p+1}$ =, ...,  $T_q$ =, [...]) : R

if **U** is a subtype of **R** and  $n \le p$  and  $S_i$  is equivalent to  $T_i$  for all i in 1..min(q,m). In addition:

- If neither function type has a rest argument, then we require that  $q \le m$ .
- If only the first function type has a rest argument, then no additional conditions are needed.
- If only the second function type has a rest argument, then subtyping does not hold.
- If both function types have a rest argument, then  $\mathbf{S_i}$  must be equivalent to the any type \* for all i in  $(q+\frac{1}{2})$
- For generic functions, alpha-renaming of the type variable preserves the meaning of types. Moreover,

```
function.<X<sub>1</sub>,...,X<sub>n</sub>> (argtypes1) : R1
is a subtype of
  function.<X<sub>1</sub>,...,X<sub>n</sub>> (argtypes2) : R2
if and only if
  function(argtypes1) : R1
is a subtype of
```

Hence, to check subtyping between generic functions, we alpha-rename the type variables to be identical in both types, and then proceed to check subtyping on the non-generic versions of the two function types.

function(argtypes2) : R2

# 3.4.5 Subtyping Array Types

- A fixed-length array type [S<sub>1</sub>, ..., S<sub>n</sub>, S] is a subtype of [S<sub>1</sub>, ..., S<sub>n</sub>]. The supertype demands one fewer element in the array than the subtype does. For example, [Number, String, Boolean] is a subtype of [Number, String].
- A fixed-length array type  $[\mathbf{S_1}, \ldots, \mathbf{S_n}]$  is a subtype of  $[\mathbf{T_1}, \ldots, \mathbf{T_n}]$  if each  $\mathbf{S_i}$  is equivalent to  $\mathbf{T_i}$  for i in 1....
- A variable-length array type [S<sub>1</sub>, ..., S<sub>n</sub>, S, ... S] is a subtype of [S<sub>1</sub>, ..., S<sub>n</sub>, ... S]. The supertype demands one fewer element in the array than the subtype does. For example, [Number, String, Boolean, ... Function] is a subtype of [Number, ... Function] via transitivity.

NOTE Since . . . denotes concrete syntax, we use the *meta-syntax*  $S_1$ , . . .  $S_n$  to denote a sequence of zero-or-<u>more comma-separated</u> types.

- 4 A variable-length array type  $[S_1, \ldots, S_n, \ldots, S]$  is a subtype of  $[T_1, \ldots, T_n, \ldots, T]$  if **S** is equivalent to **T** and if each  $S_i$  is equivalent to  $T_i$  for i in 1....
- Via transitivity, the above rules may be applied multiple times, in various combinations. The following code combines all of these rules into a single deterministic algorithm for array subtyping.

**Semantics** 

```
and subTypeArray extra type1 type2 =
   case (type1, type2) of
       (ArrayType (types1, rest1),
        ArrayType (types2, rest2))
       let
           val min = Int.min( length types1, length types2 )
           List.take(types2, min))
           andalso
           (case (rest1, rest2) of
                         NONE ) => length types1 >= length types2
                (NONE.
                             _ ) => false
                (NONE
                         SOME
                (SOME
                         NONE
                                ) => false
                (SOME \overline{t1}, SOME t2) =>
                length types1 >= length types2 andalso
                equivType extra t1 t2 andalso
                List.all (fn types1 => equivType extra type1 t2)
                        (List.drop(types1, length types2)))
       end
     | _ => false
```

# 3.4.6 Subtyping Union Types

```
A union type (\mathbf{S_1} \mid \dots \mid \mathbf{S_n}) is a subtype of a type \mathbf{T} if \mathbf{S_i} is a subtype of \mathbf{T} for all i in 1..n.
```

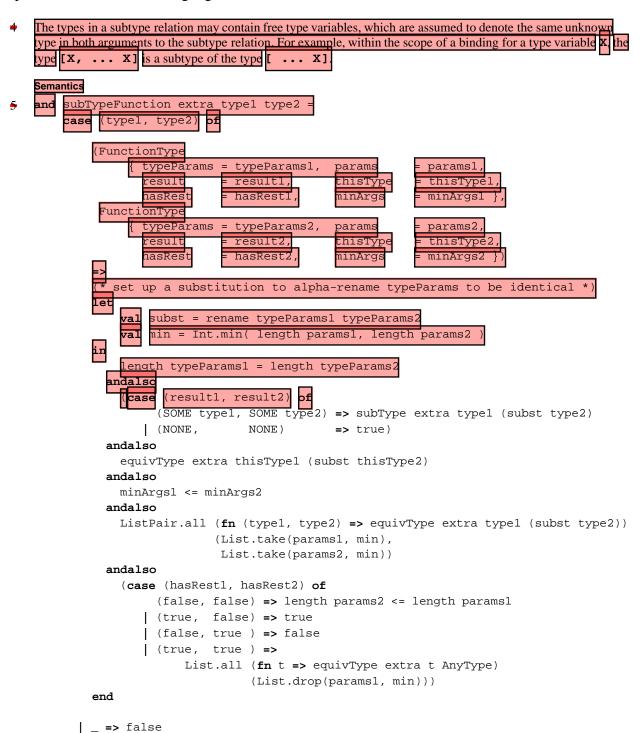

A type **S** is a subtype of  $(\mathbf{T}_1 \mid \ldots \mid \mathbf{T}_n)$  if there exists some i in 1...n such that **S** is a subtype of  $\mathbf{T}_{i}$ .

```
Semantics
```

```
and subTypeUnion extra type1 type2 =
    case (type1, type2) of

        (UnionType types1, type2)
        => List.all (fn type1 => subType extra type1 type2) types1

        (type1, UnionType types2)
        => List.exists (fn type2 => subType extra type1 type2) types2
```

The following function rename performs the capture-free substitution of references to any of the identifiers in typeParams1 with references to the corresponding identifier in typeParams2 in the type ty.

#### **Semantics**

# 3.3.8 Subtyping Non-Null Types

- 1 A non-null type 1S is a subtype of type T if S is a subtype of the union type (T | null).
- 2 A type S is a subtype of a non-null type +T if S is a subtype of T and the type null is not a subtype of S.

=> false

# 3.4.7 Subtyping Function Types

A function type  $\mathbf{function}(\mathbf{S_1}, \ldots, \mathbf{S_n}) : \mathbf{U}$  is a subtype of  $\mathbf{function}(\mathbf{T_1}, \ldots, \mathbf{T_n}) : \mathbf{R}$  if  $\mathbf{U}$  is a subtype of  $\mathbf{R}$  and  $\mathbf{S_i}$  is equivalent to  $\mathbf{T_i}$  for all i in 1..m.

NOTE Function subtyping is invariant in the argument position, and covariant in the result type.

This rule generalizes to **this** arguments, default arguments, and rest arguments according to the following rule, where the number of default arguments (indicated via the = symbol) in each function type may be zero, and where [...] indicates an optional rest argument. A function type

$$\texttt{function(this:S}_1, \ \textbf{S}_2, \ \dots, \ \textbf{S}_n, \ \textbf{S}_{n+1} \texttt{=}, \ \dots, \ \textbf{S}_{\texttt{m}} \texttt{=}, \ [\dots]) \ : \ \textbf{U}$$

is a subtype of

$$\texttt{function(this:T}_1, \ \texttt{T}_2, \ \dots, \ \texttt{T}_p, \ \texttt{T}_{p+1} \texttt{=}, \ \dots, \ \texttt{T}_q \texttt{=}, \ [\dots]) \ : \ \texttt{R}$$

if  $\mathbf{U}$  is a subtype of  $\mathbf{R}$  and  $n \le p$  and  $\mathbf{S}_i$  is equivalent to  $\mathbf{T}_i$  for all i in 1..min(q,m). In addition:

- If neither function type has a rest argument, then we require that  $q \le m$ .
- If only the first function type has a rest argument, then no additional conditions are needed.
- If only the second function type has a rest argument, then subtyping does not hold.
- If both function types have a rest argument, then  $\mathbf{S}_i$  must be equivalent to the any type \* for all i in (q+1), m.
- 3 For type-parametric functions, alpha-renaming of the type variable preserves the meaning of types. Moreover,

```
function.\langle X_1, ..., X_n \rangle (argtypes1) : R1
```

is a subtype of

function.
$$\langle X_1, ..., X_n \rangle$$
 (argtypes2) : R2

if and only if

function(argtypes1) : R1

is a subtype of

```
function(argtypes2) : R2
```

Hence, to check subtyping between type-parametric functions, we alpha-rename the type variables to be identical in both types, and then proceed to check subtyping on the non-type-parametric versions of the two function types.

```
The types in a subtype relation may contain free type variables, which are assumed to denote the same unknown type in both arguments to the subtype relation. For example, within the scope of a binding for a type variable X, the type [X, ... X] is a subtype of the type [... X]
```

Semantics

and subTypeFunction extra type1 type2

```

#### Cemantics

# **3.3.9 Subtyping Nullable Nominal Types**

4 A nominal type  $\Theta$  (or  $\Theta \cdot \langle T_1, \cdots, T_n \rangle$ ) can be declared as a non-null type via any of the following declarations:

```
class C: ...
class C: Y, ..., Y Y ...
interface C: ...
interface C: X, ..., Y Y ...
```

- 2 A nominal type is *natlable* if it is not a non-null type.
- 3 The type null is a subtype of any nullable nominal type.

#### **Comanties**

# 3.3.10 Subtyping Nominal Types

Given a class definition

```
class C extends D implements I_1, ..., I_n { ... }
```

the type  $\mathbf{C}$  is a subtype of  $\mathbf{D}$ , and  $\mathbf{C}$  is also a subtype of  $\mathbf{I}_{\mathbf{i}}$  for  $\mathbf{j}$  in 1..n.

Given an interface definition

```
interface K extends I_1, ..., I_n \{ ... \}
```

```
(SOME type1, SOME type2) => subType extra type1 (subst type2) (NONE, NONE) => true)
    andalso
       equivType extra thisType1 (subst thisType2)
    andalso
       minArgs1 <= minArgs2
     andalso
       ListPair.all (fn (type1, type2) => equivType extra type1 (subst type2))
                       (List.take(params1, min),
                        List.take(params2, min))
    andalso
       (case (hasRest1, hasRest2) of
     (false, false) => length params2 <= length params1</pre>
             (true, false) => true
(false, true) => false
(true, true) =>
                  List.all (fn t => equivType extra t AnyType)
                              (List.drop(params1, min)))
  end
| _ => false
```

The following function rename performs the capture-free substitution of references to any of the identifiers in typeParams1 with references to the corresponding identifier in typeParams2 in the type ty.

#### Semantics

## 3.4.8 Subtyping Nominal Types

1 Given a class definition

```
class C extends D implements I_1, \ldots, I_n \{ \ldots \}
```

the instance type  $\mathbf{C}$  is a subtype of instance type  $\mathbf{D}$  and instance type  $\mathbf{C}$  is also a subtype of interface type  $\mathbf{I}_{\mathbf{i}}$  for  $\mathbf{j}$  in 1....

2 Given an interface definition

```
interface K extends I_1, \ldots, I_n \{ \ldots \}
```

the type  $\mathbf{K}$  is a subtype of  $\mathbf{I}_{\mathbf{i}}$  for  $\mathbf{j}$  in 1..m.

These rules generalize to applications of type-parametric instance and interface types via appropriate renaming of bound variables. For example, given a type-parametric interface type defined by

```
class C.<x_1, ..., x_n> extends D.<T_1, ..., T_m> { ... } we have that C.<S_1, ..., S_n> is a subtype of
```

$$\texttt{D.} < \texttt{T}_1[\, \texttt{x}_1 \colon = \texttt{S}_1 \,, \, \ldots \,, \, \texttt{x}_n \colon = \texttt{S}_n] \,, \quad \ldots \,, \quad \texttt{T}_m[\, \texttt{x}_1 \colon = \texttt{S}_1 \,, \, \ldots \,, \, \texttt{x}_n \colon = \texttt{S}_n] >$$

4 Also,  $\mathbf{C} \cdot \langle \mathbf{T_1}, \ldots, \mathbf{T_n} \rangle$  is a subtype of  $\mathbf{C} \cdot \langle \mathbf{S_1}, \ldots, \mathbf{S_n} \rangle$  if each type  $\mathbf{T_i}$  is equivalent to the corresponding type  $\mathbf{S_i}$  for i in 1..n.

NOTE The notation  $\mathbf{T}[\mathbf{x}_1 := \mathbf{S}_1, \dots, \mathbf{x}_n := \mathbf{S}_n]$  denotes the type  $\mathbf{T}$  with each occurrence of the type variable  $\mathbf{x}_i$  replaced (in a capture-free manner) by the corresponding type  $\mathbf{S}_i$ .

NOTE. The above rules also apply if C is declared as a non-nullable instance type

NOTE. There is a distinction between the type name **C** and the instance type to which it refers in that the type name **C** includes the type **null** if **C** is a nullable type, whereas the instance type **C** describes only class instances.

```
and subTypeNominal extra type1 type2 =
case (type1, type2) of
```

```
( InstanceType (Class { typeParams = [], extends, implements, ...}), _ )
=> (case extends of
```

the type K is a subtype of IJ for j in 1..m.

These rules generalize to applications of generic classes and interfaces via appropriate renaming of bound variables. For example, given a generic class definition

```
we have that C.<s_1, ..., s_n> extends D.<T_1, ..., T_m> { ... }
```

$$D.$$

Also,  $C \cdot < T_1$ , ...,  $T_n >$  is a subtype of  $C \cdot < S_1$ , ...,  $S_n >$  if each type  $T_i$  is equivalent to the corresponding type  $S_i$  for i in 1...n.

```
NOTE The notation T[x_1:=S_1, \dots, x_n:=S_n] denotes the type T with each occurrence of the type variable x_1 replaced (in a capture free manner) by the corresponding type S_1.

## 3.4.9 Relating Structural and Nominal Types

- A record type  $\{N_1:S_1, \ldots, N_n:S_n\}$  is a subtype of the instance type **public**::0bject.
- 2 An array type [S<sub>1</sub>, ..., S<sub>n</sub>] is a subtype of the instance type **public::Array** which is a subtype of the instance type **public::Object**.
- Any function type is a subtype of the instance type public::Function, which is a subtype of the instance type public::Object.

```
Semantics
```

: TYPE

= ...

The following function substTypes performs the capture-free replacement of all occurrences of typeParams by typeArgs within the type ty.

# 3.3.11 Relating Structural and Nominal Types

- + A record type  $\{N_1:S_1, ..., N_n:S_n\}$  is a subtype of the class type public::Object.
- An array type  $[S_1, \ldots, S_n]$  is a subtype of the class type **public::Array**.
- Any function type is a subtype of the class type **public::Function**.

### Semantics

# 3.4 Type Normalization

At run-time, when a type is encountered in the source program, that type is immediately normalized. Type normalization consists of two phases: type resolution followed by type canonicalization.

# 3.4.1 Type Resolution

- † Type resolution on a type **P** proceeds as follows:
- In the scope of a type definition

```
any reference to a type variable x in T is replaced by the type
```

```
=> nameEq name Name.public_Array orelse
   nameEq name Name.public_Object

| (FunctionType _, InstanceType (Class { name, ... }))
=> nameEq name Name.public_Function orelse
   nameEq name Name.public_Object

| => false
```

# 3.5 Compatible Types

The *compatibility* relation is a binary relation on type values. A type  $\mathbf{S}$  is compatible with a type  $\mathbf{T}$  if  $\mathbf{T}$  can be obtained from  $\mathbf{S}$  by replacing certain portions of  $\mathbf{S}$  by the any type \*.

For example, the record type {x : double} is compatible with both {x : \*} and with \*, but the type {x : \*} is not compatible with {x : double}.

Also, T. < Number > is compatible with T. < \* >.

This compatibility relation is reflexive and transitive, but not symmetric.

# 3.6 Compatible-Subtyping

The *compatible-subtype* relation is a binary relation on types. A type **s** is a compatible-subtype of a type **T** if there exists some type **U** such that **S** is a subtype of **U** and **U** compatible with **T**.

```
For example, the record type {x : double. v : boolean} is a compatible-subtype of the types {x : *, y : *}, {x : double} {x : *}, and *.
```

The compatible-subtyping relation is reflexive and transitive, but not symmetric.

The compatible-subtyping relation is implemented by calling the previously-defined subType predicate and passing in an extra parameter that implements the compatibility relation, that every type is compatible with \*.

### Semantics

```
fun compatibleSubtype (type1 : TYPE) (type2 : TYPE) : bool =
    subType
          (fn type1 => fn type2 => type2 = AnvTvpe)
          type1 type2
```

# 3.7 Type Invariants at Run Time

A type is *allocatable* if it is not the any type or a union type.

Every value in ES has an associated *allocated type*, which is a type that is associated with the value when the value is first allocated or created. An allocated type is always an allocateble type. The allocated type of a value is invariant; for example, updating the fields of an object cannot change the allocated type of that object.

If a property of storage type  ${\bf T}$  hold a value  ${\bf v}$  of type  ${\bf S}$ , then  ${\bf S}$  is a compatible-subtype of  ${\bf T}$ .

## 4 Names

2

Names in ECMAScript are defined in section ... names.

Names are used to identify properties within property maps and fixtures within fixture maps.

A name is calculated from a name expression found in ECMAScript source code.

# 4.1 Name Expressions

- 1 A name expresison is either qualified or unqualified
- 2 A qualified name expression consists of a namespace expression and an identifier. The former is either a literal namespace value (resulting from using a string as a namespace qualifier) or else a further name expression identifying a namespace fixture in the lexical environment. Examples of a qualified names are intrinsic::subtring or "org w3.dom"::DOMNode
- 3 An unqualified name expression consists of an identifier and a list of sets of open namespaces, determined by context. An example of an unqualified name is encodeURL

3 In the scope of a generic type definition

type X. \( y\_1, \ldots, y\_n \rangle = S \)

a type application X. \( S\_1, \ldots, y\_n \rangle = S \)

a type application  $x < s_1$ , ...,  $s_n > in T$  is replaced by the type  $s[y_1 := s_1]$ , ...,  $y_n := s_n]$ .

In the scope of a class definition that associates a class name with a class definition s, type resolution replaces any TypeName that refers to s with s with s class s type s.

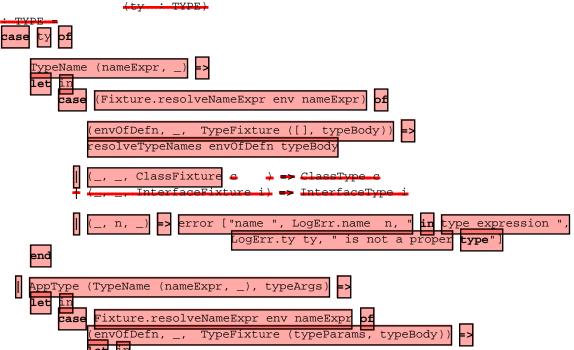

6 The type resolution code is not presented here.

# 3.4.1.1 Implementation of Type Resolution

- The following function resolveTypeNames performs type resolution on a particular type by in the context of an environment by:
- This function relies on the auxiliary function Fixture.resolveNameExpr (described in section ...) to resolve each type name. The function Fixture.resolveNameExpr returns the corresponding fixture (as the third component of the result triple), plus the environment that fixture was defined in, and the fully-resolved name for the given name expression.
- If the resulting fixture is for a non-parametric type definition, the body of that type definition is resolved in its environment, and then replaces the original type name.
- 4 If the resulting fixture is for a class or interface definition, the type name is replaced by a class type or an interface type.
- A type application that refers to a type-parametric type definition is replaced by the body of that type definition, after the replacement of each formal parameter name with the corresponding resolved type argument.
- If none of the above cases apply, then resolveTypeNames uses the helper function mapType to perform type name resolution on each sub-term of the given type.
- The function error messages, and the module LogErr contains functions for converting various data structures into corresponding Strings.

#### Semantics

fun resolveTypeNames (env : RIBS)

- An unqualified name is subject to name resolution, and must resolve to a unique qualified name. The algorithm for name resolution is presented in subsequent sections, and differs depending on the context the unqualified name occurs within
- Names that are used in contexts denoting types and namespaces must be resolved statically at definition time. Names that denote other properties may be resolved repeatedly at evaluation time.

NOTE In a qualified name such as intrinsic::substring the leftmost identifier, intrinsic, is itself unqualified and subject to definition-time resolution.

#### Semantics

```
and NAME_EXPRESSION =
OualifiedName of {
                              namespace: NAMESPACE EXPRESSION.
                               identifier: IDENTIFIER }
{ identifier: IDENTIFIER
    UnqualifiedName of
                                  openNamespaces: OPEN NAMESPACES }
```

```
and NAMESPACE EXPRESSION =
    Namespace of NAMESPACE
   NamespaceName of NAME EXPRESSION
```

#### <u>4.1.1</u> Open namespaces list

The open pamespaces list of an unqualified name expression is a list of sets of namespaces open at the point of the program where the name expression occurs and is ordered by priority with sets of namespaces earlier in the list taking priority over sets later in the list. The list reflects the nesting of lexical scopes, with the namespaces opened in the "innermost" lexical scope held in the first set of namespaces in the list, and subsequent sets holding namespaces opened in enclosing lexical scopes

#### Semantics

type NAMESPACE SET =

type OPEN NAMESPACES = NAMESPACE SET list

#### 4.1.2 Special namespaces

- Several namespaces are assigned special meaning, and are generated by an ECMAScript implementation in specific contexts.
- These namespaces are bound to predefined names and implicitly opened in their associated scopes. In the following sections. when a namespace is said to be *implicitly opened* in a given lexical scope, the specified meaning is that a new namespace set is added to the front of the open namespaces list for the duration of the scope containing the implicitly opened namespaces.

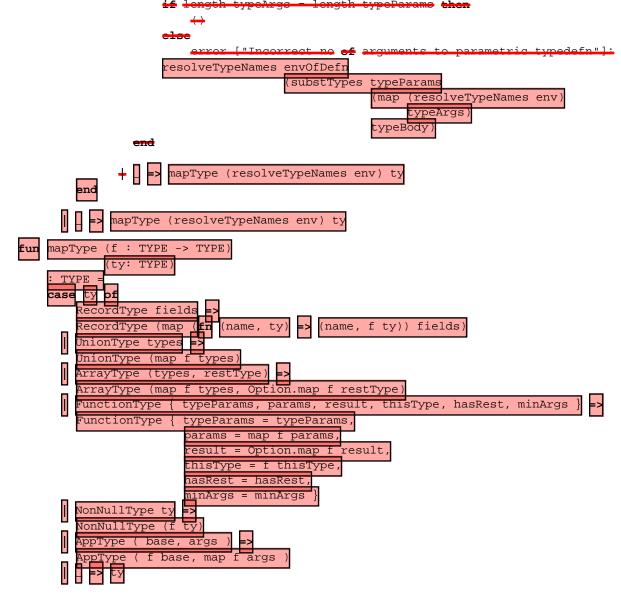

### Public and 4th Edition namespaces

- The public and 4th Edition namespaces are defined in section Standard Namespaces of Values, and are defined identically in all programs and lexical scopes
- The 4th Edition namespace is bound to the global property name "":: ES4 (that is, the name formed by qualifying the identifier FS4 with the public namespace) and can therefore be seen by code loaded in either 3rd Edition or 4th Edition mode.
- The public namespace is bound to the global property name **ES4** ::public (that is, the name formed by qualifying the identifier public with the 4th Edition namespace)
- When a program is loaded in 3rd Edition or 4th Edition mode, the public namespace is implicitly opened.
- When a program is loaded in 4th Edition mode, after the public namespace is implicitly opened, the 4th edition namespace is implicitly opened. The 4th Edition namespace is therefore opened at a higher priority than the public namespace.

**NOTE** The **public** namespace is distinguished in several ways. The names of properties added dynamically to objects are qualified by **public** by default, so all properties created by 3rd Edition code running on a 4th Edition implementation are **public**, and **public** is sometimes called "the compatibility namespace" for that reason. The default namespace qualifier that is applied to declarations in every scope is **public**, so absent other qualification every property on every object and every lexically bound name is in the public namespace.

#### 4.1.2.2 Internal namespaces

- Each program (compilation unit) has a new implementation-generated opaque namespace implicitly defined as its internal namesnace at the start of the definition phase
- The internal namespace for a program is bound to the name **internal** in the global fixture man for the duration of definition and evaluation. The binding to internal is removed after definition and evaluation of a program, and is re-bound to new internal namespaces for any subsequent programs loaded

# 3.4.2 Type Canonicalization

- Each type ∓ is considered equivalent (under the equivalence relation defined above) to some collection of types. The process of type canonicalization converts a type in the program source code into a canonical or representative element of its equivalence class. In particular, if two types T₁ and T₂ are equivalent, then canonicalization will convert them both into an identical normalized type.
- 2 This canonicalization process is necessary to efficiently support type-parametric classes.
- 3 The type canonicalization code is not presented here.

### 3.4.3 Normalized Types

- A normalized type is one that is the result of the preceeding normalization process.
- Normalized types do not include:
  - type names that refer to nominal types (ClassType and InterfaceType are used instead)
  - type names that refer to type definitions (which are inlined)
- Normalized types may include type names that refer to generic type parameters; these references include a nonce.

# 3.5 Compatible Types

When a program is loaded in 4th Edition mode, after the 4th Edition namespace is implicitly opened, the program's internal namespace is implicitly opened. The internal namespace is therefore opened at a higher priority than the 4th Edition namespace.

NOTE. An internal namespace can be used to qualify definitions that are not intended to be visible to any other program.

### 4.1.2.3 Private and protected namespaces

- Each class definition has two new implementation-generated opaque namespaces implicitly defined as its private namespace and protected namespace.
- The private and protected namespaces for a class are bound to the names private and protected respectively within the lexical scope of the class definition they are associated with
- The private and protected namespaces for a class are implicitly opened within the lexical scope of the class.
- The protected namespace for a class C is also implicitly opened within the lexical scope of every class that extends C

### 4.2 Reference Expressions

- A reference expression provides context for resolving a name expression to a name, and identifying a particular fixture or property to which the name refers. A reference expression is either a lexical reference, an object name reference, or an object index reference.
- A lexical reference is a reference expression that resolves to a name within a lexical scope, and therefore a property or fixture stored in a scope object. Some lexical references are required to be resolved to fixtures statically during program definition, while others may be resolved dynamically during program evaluation. Examples of lexical references are encodeURL or public::Function.
- An object name reference is formed by conjoining an object expression and a name expression with a period (" "). A name expression in an object name reference resolves to the name of a fixture or property on the provided object, or a fixture or property on the object's prototype chain. Some object references may be resolved to fixtures statically, but the specified behavior of object references is as if they are always resolved dynamically during program evaluation. Examples of object references are sclength or scintrinsic::substring, where s is the name of an object.
- An object index reference is similar to an object name reference, in that it combines an expression for a name with an object and resolves the calculated name against the provided object. An object index reference differs from an object name reference by the fact that there is no proper name expression inside it: rather an object expression is conjoined with a general ECMAScript expression, enclosed within square brackets, and determining the name to resolve may require arbitrary evaluation of the bracketed expression. An example of an object index reference is s[f()], where s is the name of an object, and the name to be resolved against s is calculated dynamically by evaluating the function expression f(). Object index expressions can therefore never be resolved statically.

```
datatype EXPRESSION =

LexicalReference of { name: NAME EXPRESSION }

ObjectNameReference of { object: EXPRESSION, name: NAME expression,
```

# 4.3 Lexical scopes

- Lexical scopes are defined in section ... scopes.
- 2 Defining and binding forms introduce names into a lexical scope. These names are then visible to lexical references that seems within the scope of the binding. The scope of a binding is primarily determined by the textual boundaries of the scope (ECMAScript is primarily lexically scoped) and depends also on the defining or binding form that introduced the binding.

NOTE For example, the scope of a var pinding inside a block statement is the entire body of the function or program containing the block, whereas the scope of a let pinding inside a block statement is that block statement.

- Scopes nest textually, and a name that is bound in one scope may be *shadowed* in an inner scope by a binding of the same name in the inner scope; name expressions in the inner scope will not be able to access the outer binding.
- 4 In this specification, he nesting of scopes is modelled as a list of fixture maps in the definition phase and a list of objects during evaluation. The former list is called the static scope chain or the static environment. The latter list is called the

- The compatibility relation is a binary relation on type values. Two types s and T are compatible if T can be obtained from S by replacing certain portions of S by the any type \*.
- For example, the record type {x : int} is compatible with both {x : \*} and with \*, but the type {x : \*} is not compatible with {x : int}.
- Also, T. < Number > is compatible with T. <\*>.
- This compatibility relation is reflexive and transitive, but not symmetric.

# 3.6 Compatible-Subtyping

- The compatible-subtype relation is a binary relation on types. A type S is a compatible-subtype of a type T if there exists some type U such that S is a subtype of U and U compatible with T.
- For example, the record type  $\{x : int, y : bool\}$  is a compatible subtype of the types  $\{x : *, y : *\}, \{x : int\}, \{x : *\}, and *.$
- The compatible-subtyping relation is reflexive and transitive, but not symmetric.
- The compatible-subtyping relation is implemented by calling the previously-defined subType predicate and passing in an extra parameter that reasons about compatibility, in that every type is compatible with \*.

#### Semantics

```
fun compatibleSubtype (type1 : TYPE) (type2 : TYPE) : bool =
    subType
        (fn type1 => fn type2 => type2 = anyType)
        type1 type2
```

# 3.7 Type Invariants at Run Time

- A type is reifiable if it is not the any type or a union type.
- Every value in ES has an associated *allocated type*, which is a type that is associated with the value when the value is first allocated or created. An allocated type is always a reifiable type. The allocated type of a value is invariant; for example, updating the fields of an object cannot change the allocated type of that object.
- If a property of storage type T hold a value v of type S, then S is a compatible-subtype of T.

# 4 Names

- Names in ECMAScript are constants that are comprised of a namespace value and an identifier.
- Names denote types, namespaces, and locations (properties bound in objects and scopes). The denotation of a name depends on the context of the name's use: When a name is used in a type annotation context it denotes a type; when it is used in a qualifier context it denotes a namespace, and in all other contexts it denotes a location.
- Unqualified names are expressed as simple identifiers, for example encodeURI. Qualified names are expressed as pairs of namespace expressions and simple identifiers, for example intrinsic::substring or "org.w3.dom"::DOMNode.
- 4 Unqualified names are subject to name resolution: every unqualified name must resolve to a unique qualified name. Names that denote types and namespaces are resolved at definition time, while names that denote locations are resolved (repeatedly) at evaluation time.
  - NOTE In a qualified name such as intrinsic: substring the leftmost identifier, intrinsic, is itself unqualified and subject to definition-time resolution.
- Name resolution makes use of the *open namespaces* that implicitly qualify any unqualified name. In every compilation unit the open namespaces starts out being comprised of the **public** and **internal** namespaces. The program can open additional namespaces by means of the use namespace pragma.
- Name resolution is performed differently depending on whether the name is a lexical reference (for example, the variable reference encodeURI) or a property reference on an object (for example, the reference substring)

dynamic scope chain or the dynamic environment. Both lists are generically referred to as scope chains, with the distinction between the static and dynamic environments indicated where not otherwise clear from context.

- 5 Each scope holds a fixture man of the named fixtures defined in that scope
- 6 The fixture maps in the static environment are arranged into a simple list.

#### **Semantics**

- 7 and FIXTURE\_MAPS = ((FIXTURE\_NAME \* FIXTURE) list) list
- 8 The fixture maps in the dynamic environment are arranged into accompanying objects, each with a corresponding property map in which values may be stored as properties.

#### Semantics

9 and SCOPE =

and SCOPE\_KIND =

WithScope

GlobalScope

InstanceScope of CLASS

ClassScope

ActivationScope

BlockScope

TypeArgScope

EvalScope

- 10 At each point in the program, both during definition and evaluation, exactly one scope chain is in effect. This scope chain is called the scope chain or the environment containing an expression, statement or definition.
- Some objects that appear on evaluation time scope chains are dynamically extensible. For example, class objects appear on the scope chain of class and instance methods, and properties can be added to and removed from class objects however, these properties are not visible to lexical references within the class.

### 4.3.1 Prototype chain

- 1 Every object has a distinguished value called its *prototype* (see section Object prototype in Values).
- 2 If the prototype value of an object is another object, then the prototype value is called the object's *prototype object*, and the connection between the initial object and its prototype object is called its *prototype link*.
- 3 The *prototype chain* is the list of objects formed by following prototype links from an object. The prototype chain of an object begins with the object itself, and ends with the first object having a null prototype value.
- When a name is to be resolved against an object, if resolution initially fails because the object does not contain a property matching the name, then resolution continues along the object's prototype chain.

## 4.4 Name Resolution

### 4.4.1 Overview

- 1 The purpose of name resolution is to take an unresolved name and a list of objects and return an unambiguous name (consisting of a namespace value and an identifier) and an object that contains a property with that name. The objects are searched in order, and the first object to contain a property with the name is selected.
- There are two complications. The first appears with the need for disambiguation. When an unqualified name is resolved the resolution is performed in the context of the namespaces that were open at the point of reference. Thus the search of any one object may find multiple bindings that match the name, up to one binding per open namespace. Instead of making this argories, the name resolver disambiguates by trying to select the most desirable of those namespaces. Selection is performed by attering the applicable namespaces until we are left with one. (If we have more than one then the name is deemed ambiguous.)
- We first select those namespaces among the matching namespaces that are in use by the least specific class of the object that contains the name. For example, if the problem is a subclass of the name in the name in the name in the name in the name is a subclass of the name in the na

- In the case of a lexical reference a name is resolved as a reference to a name bound in the scope of the reference, each entry in the chain formed by active scope objects binds names to which the reference may resolve, with resolutions in scopes closer to the point of reference (in "inner scopes") preferred over those in scopes further away (in "outer scopes").
- In the case of a property reference a name is resolved as a reference to a property on a specific object, each entry in the chain formed by the object and its prototype objects in order provides named properties to which the reference may resolve, with resolutions in objects closer to the original object preferred over those further out in the prototype chain.
- A reference may be found to be ambiguous. The resolution algorithm incorporates several forms of disambiguation, described later, but some references are inherently ambiguous. Such references cause errors to be signalled at definition or evaluation time.
- Names that denote types, namespaces, and locations are resolved by the same algorithm. Suppose an unqualified name that denotes a type or namespace is resolved to a particular type or namespace definition in a particular scope. Then the same unqualified name denoting a location will be resolved unambiguously to an immutable location that holds a value that represents the type or namespace, if resolution takes place in the same scope as for the first name. A reservation mechanism ensures that names that are resolved at definition time cannot become ambiguous at evaluation time by the introduction of new bindings.

### 4.1 Name Values

A name is a constant value comprised of a namespace value and an identifier.

#### Competing

- 2 type NAME { ns. NAMESDACE, id. IDENTIFIER }
- 3 An identifier is a character string.

#### Comantics

- 4 type IDENTIFIER Ustring.STRING
- A namespace value is an immatable object. A namespace is transparent or opaque. A transparent namespace contains a character string that identifies the namespace, two transparent namespaces are equal if and only if their contained strings are equal. An opaque namespace contains an unforgeable system-generated value that identifies the namespace; two opaque namespaces are equal if and only if their contained identifier values are the same object.

#### **Comunties**

```
datatype NAMESDACE -
```

TransparentNamespace of Ustring STRING

→ OpaqueNamegrage of ODAQUE NAMEGRAGE IDENTIFIED

```
COPE ODNOUS NAMESDACE IDENTIFIED -
```

```
fun compareNamespaces (nl: NAMESDACE, n2: NAMESDACE) : bool =
```

case (n1, n2) of

(Ast TransparentNamespace s1, Ast TransparentNamespace s2) → s1 - s2

+ (Ast OpaqueNamespace il, Ast OpaqueNamespace i2) → il - i2

 + → false

# 4.2 The namespace public

1 The namespace known as public is the transparent namespace whose identifying string is the empty string.

# <del>Comantics</del>

2 val publicNS - Act TransparentNamespace Ustring empty

**NOTE** The **public** namespace is distinguished in several ways. The names of properties added dynamically to objects are qualified by **public** by default, so all properties created by 3rd Edition code running on a 4th Edition implementation are **public**, and **public** is sometimes called "the compatibility namespace" for that reason. The default namespace qualifier that is applied to declarations in every scope is **public**, so absent other qualification every property on every object and every lexically bound name is in the **public** namespace.

## 4.3 Prototype chain

- (The motivation for using the order in which names are introduced in the class hierarchy is to guarantee that the meaning of valid references to object properties doesn't change. In other words, if **o.x** is ever valid, then it shall always refer to the same property **x** as long as the type of **o** doesn't change.)
- We then filter by namespace priority. The open namespaces are organized in a prioritized list of namespace sets. If one of the matching names has a namespace that is from a set with a higher priority than all the other matching names, then that's the namespace we want. So if the referencing context of **n** opened **ns2** in a scope nested inside the one that opened **ns1**, then we are left with just **ns2** and a single binding, **ns2::n**.
- 6 (The motivation for disambiguation by the scope in which a namespace is opened is simple: it allows more programs to run. Furthermore, since the priority of namespaces during disambiguation is under the control of the programmer, the programmer can rely on disambiguation to control which names are found.)
- The second complication is that some names are required to be resolved successfully at definition time -- names that denote namespaces and types. (We require definition-time resolution in order to make names and types constant, which generally simplifies the language and makes programs more easily comprehensible.) The consequence is that namespace and type references are illegal inside scopes introduced by with or scopes that may be extended by the eval operator, because those scopes make definition time resolution impossible -- their contents are unknown. Such programs result in a syntax error being signalled. (It is possible to ease that restriction in various ways but we have not done so.)
- However, we also require that type and namespace names that are resolved at definition time must resolve to the same bindings that they would resolve to if they were to be resolved at evaluation time. (We require that because it simplifies the user's model of the language: equal names in the same scope have the same meaning, provided they resolve at all.) The consequence is that the language must provide protection against ambiguities that can be introduced at a later time. If a name is resolved at definition time to a global binding then compilation units loaded later may introduce new global bindings that will make the resolved binding ambiguous. For example, consider the following program.

```
namespace NS1
namespace NS2
NS1 type T
use namespace NS1, namespace NS2
... var x: T
```

9 The reference to **T** in the type annotation is resolved uniquely at definition time to **NS1::T**. Then another compilation unit is loaded:

```
NS2 type T = ...
```

- 10 Since the global environment is "flat"--code in earlier compilation units can see bindings introduced by later compilation units--the reference to **T** from the first program is now ambiguous.
- 11 ES4 protects against this eventuality by *reserving* global names that are resolved at definition time. When **T** is resolved in the first program and found to be in **NS1**, the name **NS2::T** is reserved: it is made off-limits to later programs. As a consequence, the second program above would not be loaded, because the introduction of **NS2::T** would be an error.
- 12 Names are reserved in namespaces at the same or higher priority level as the namespace that the name was resolved to, so in the example above neither **public::**T nor **internal::**T would become reserved, as those namespaces are at lower priority levels than **NS1** and **NS2**.

NOTE. Top-level "use namespace" pragmas are given a higher priority level than names originating "outside" the compilation unit, as is the case for

# 4.4.2 Definition-Time Resolution of Namespace and Type Expressions

- The definition time scope chain is modelled as a list of fixture maps, defined elsewhere. A fixture map maps names to fixture bindings that result from defining and binding forms (var, function, type, class, interface, namespace, and others) Fixture maps have no dynamic properties.
- 2 Definition time resolution resolves name expressions that denote namespaces and types, and performs reservation of global names if necessary.
- The following algorithm resolves a name expression to a specific name and fixture in the list of fixture maps.

#### Semantics

4 and resolveNameExpr (fixtureMaps : Ast.FIXTURE MAPS)

```
(ne
: (Ast.FIXTURE MAPS * Ast.NAME * Ast.FIXTURE) =
case ne of
```

- Every object has a distinguished value called its *prototype* (see section Object prototype in Values).
- If the prototype value of an object is another object, then the prototype value is called an object's *prototype object*, and the connection between the initial object and its prototype object is called a *prototype link*.
- The *prototype chain* is the list of objects formed by following prototype links from an object. The prototype chain of an object begins with the object itself, and ends with the first object having a null or undefined prototype value.
- When a name is to be resolved against an object, if resolution initially fails because the object does not contain a property matching the name, then resolution continues along the object's prototype chain.

# 4.4 Scopes and visibility

Defining and binding forms introduce names into a program. These names can be referenced by name expressions that occur within the *scope* of the binding. The scope of a binding is primarily determined textually (ECMAScript is primarily *lexically scoped*) and depends also on the defining or binding form that introduced the binding.

NOTE For example, the scope of a voice binding inside a block statement is the entire body of the function or program containing the block whereas the scope of a let binding inside a block statement is that block statement.

- Scopes nest textually, and a name that is bound in one scope may be *shadowed* in an inner scope by a binding of the same name in the inner scope; name expressions in the inner scope will not be able to access the outer binding.
- In this Specification, the nesting of scopes is modelled as a list of ribs in the definition phase and a list of objects during evaluation. Both environments are generically called the *scope chain*. Which kind of list is being referred to will be clear from the context in which the term is used.
- Each scope holds a table of named bindings in that scope. Ribs hold a table of fixture bindings and objects hold a table of property bindings. Every time a new scope is entered the scope chain is extended with a new rib or object, and at every point in the program one particular scope chain is in effect.

FIXNE What's a fixture? Is it defined somewhere?

FIXITE Exhibit the definition time and evaluation time structures for scope chains here.

- Some objects that appear on evaluation-time scope chains are dynamically extensible, in effect providing a form of dynamic scope. For example, class objects appear on the scope chain of class and instance methods, and properties can be added to and removed from class objects: these properties then become visible and invisible to the methods.
- In order for ECMAScript to have a lexically scoped flavor, bindings that are textually visible (*texical bindings*) are usually preferred over dynamically added bindings (*dynamic bindings*) during name resolution. See the section "Name Resolution" below.

## 4.5 Name Expressions

† There are two kinds of name expressions, the unqualified name (such as encodeURI) and the namespace qualified name (such as intrinsic::subtring or "org.w3.dom"::DOMNode). Name resolution transforms name expressions into name values.

### Semantics

2 and NAME\_EXPRESSION =

```
QualifiedName of { namespace: NAMESPACE_EXPRESSION, identifier: IDENTIFIER }
UnqualifiedName of { identifier: IDENTIFIER, openNamespaces: OPEN_NAMESPACES }
```

3 A qualified name expression is comprised of a namespace expression and an identifier. The former is either a literal namespace value (resulting from using a string as a namespace qualifier) or a name expression denoting a namespace binding.

- An unqualified name expression is comprised of the namespaces that are open at the point where the name expression occurs in the source text and and identifier. The open namespaces will be used to resolve the name: an

# 4.4.2.1 Qualified Name Expressions

A qualified name expression is resolved by resolving the namespace part and then returning the tail of the list of <u>fixture maps</u> such that the first fixture map on the tail contains a binding for the name.

NOTE. The name can't be ambiguous because there is only one namespace.

#### Semantics

```
fun resolveOualifiedName (fixtureMaps
                                                      Ast.FIXTURE MAPS)
                                            : Ast. : IDENTIFIER)
                            (identifier
                            (namespaceExpr : Ast.NAMESPACE_EXPRESSION)
    : (Ast.FIXTURE MAPS
                          * NAME * Ast.FIXTURE) =
    let
         val ns = resolveNamespaceExpr fixtureMaps namespaceExpr
        val name = { ns = ns, id = identifier }
fun search (r::rs) = if hasFixture r (Ast.PropName name) then
                                    (r::rs)
                                else
                                     search rs
           | search [] = []
    in
         case (search fixtureMaps) of
             => error ["qualified name not present in fixtureMaps: ", LogErr.name name]
           L fixtureMaps'
             => (fixtureMaps'. name. getFixture (hd fixtureMaps') (Ast.PropName name))
    end
```

#### 4.4.2.2 Unqualified Name Expressions

An unqualified name expression is resolved according to the full algorithm outlined above. It returns the tail of the list of fixture maps such that the first fixture map on the tail contains an unambiguous binding for the name.

```
and resolveUnqualifiedName (fixtureMaps
                                            : IDENTIFIER)
                            (identifier
                            (openNamespaces : OPEN_NAMESPACES)
    : (Ast.FIXTURE MAPS * NAME) option =
        val namespaces = List.concat (openNamespaces)
        val matches = fixtureMapListSearch (fixtureMaps, namespaces, identifier)
    in
        case matches of
            NONE
            => NONE
          SOME (fixtureMaps, [namespace])
            => SOME (fixtureMaps, {ns=namespace, id=identifier})
          | SOME (fixtureMaps. namespaces)
            => case selectNamespaces (identifier,
                                       namespaces,
                                       [],
                                       openNamespaces) of
                   [namespace]
                   => SOME (fixtureMaps, {ns=namespace, id=identifier})
                 ns::nss
```

unqualified name matches any binding or property that has the same identifier and a namespace value from among the open namespaces.

The open namespaces are represented as a list of sets of namespace values. Each set contains namespace values that are given the same priority during name resolution. The list holds sets in priority order.

NOTE: A new set is added to the list every time a new lexical scope is entered, and the immermost (highest priority) set is extended by the USE: NOMESPACE pragma. An unqualified name expression retains a reference to the open namespaces data structure as it appears at the point where the expression occurs.

The two lowest priority sets are singleton sets holding the public and internal mannespaces, respectively. The mannespace internal is specific to each compilation unit.

#### Comenties

7 type NAMESPACE\_SET - NAMESPACE list

type OPEN\_NAMESPACES - NAMESPACE\_SET list

The first element on an ODEN\_NAMESDACES list is the highest priority element.

# 4.6 Reference Expressions

- Name expressions are incorporated into reference expressions that provide context to the name expressions. Name expressions that reference names bound in a scope, such as encodeURI and intringia: substring, are contained in Lexical Reference nodes.
- 2 Name expressions that reference properties on objects, such as g.intrinsis: substring, are contained in ObjectNameReference nodes, which contain both the object expression (s; in the example) and the name (intrinsis: substring).
- 3 Finally, the node ObjectInderReference represents names that are computed at evaluatin time, such as of the last of the last

### 4.7 Name Resolution

#### 4.7.1 Overview

- The purpose of name resolution is to take an unresolved name and a list of objects and return an unambiguous name (consisting of a namespace value and an identifier) and an object that contains a property with that name. The objects are searched in order, and the first object to contain a property with the name is selected.
- There are three complications. First, the search is performed differently for object chains (an object and its prototypes) and scope chains. An object chain is searched in a single pass and each object's fixed and dynamic properties are considered when the object is searched. A scope chain, on the other hand, is searched in two passes, with the first pass considering mainly fixed properties and the second pass considering also dynamic properties. (The search ends as soon as an object matching the name is found, so the second pass may never be run.) Thus fixed properties in outer scopes shadow dynamic properties in inner scopes. However, for reasons of compatibility with ES3, the first pass searches both dynamic and fixed properties in scopes that are introduced by the with statement or in scopes that have been extended by the eval operator evaluating a function or var directive.
- The motivation for the preference for fixed bindings in scopes is to retain the lexically scoped flavor of ECMAScript. Some of the objects on the scope chain-class objects and instance objects-are dynamically

```
=> error ["ambiguous reference: ", Ustring.toAscii identifier]
    end
fun fixtureMapListSearch ([].
    fixtureMapListSearch (fixtureMaps
                                               AST FIXTURE MAPS
                   namespaces : NAMESPACE_SET,
                   identifier : IDENTIFIER)
    : (Ast.FIXTURE MAPS * NAMESPACE SET) option =
    case fixtureMapSearch (hd fixtureMaps, namespaces,
                                                        identifier) of
        NONE
        => fixtureMapListSearch (tl fixtureMaps, namespaces, identifier)
        SOME (
        SOME (_, m)
=> SOME (fixtureMaps,
fun fixtureMapSearch (fixtureMap
                                           Ast.FIXTURE MAP,
               namespaces : NAMESPACE SET
               identifier : IDENTIFIER)
    : (Ast.FIXTURE MAP * NAMESPACE SET) option =
    case List.filter (fn ns =>
                         hasFixture fixtureMap (Ast.PropName {ns=ns, id=identifier}))
                     namespaces of
        [] => NONE
      m => SOME (fixtureMap, m)
```

#### 4.4.2.3 Reserving Names

- Statically resolved names must keep their meaning at runtime and therefore cannot be shadowed or be made ambiguous by the later introduction of names. Therefore we reserve the set of names that would cause such conflicts at runtime.
- Given a name and a list of sets of open namespaces, the following algorithm computes a set of names consisting of the identifier and each of the open namespaces with an equal or higher priority than the given namespace.

FIXME. Obviously we need more prose here. Also we want to be sure to note that reservation only happens in the global object

```
Semantics
```

## 4.4.3 Evaluation-time Resolution of Lexical References

- The evaluation time scope chain is modelled as a list of arbitrary objects. A scope object maps names to properties (both fixtures and dynamic properties). Apart from scope objects introduced by the **with** statement, the evaluation time scope chain mirrors the definition time scope chain.
- The following algorithm resolves a name expression to an object and the name of a property on that object.

#### Semantics

#### 4.4.3.1 Qualified Lexical References

To resolve a qualified lexical reference we evaluate its namespace expression (it must yield a namespace value) and then look up the name comprised of the namespace value and the qualified reference's identifier. If a binding is not found then we return the global object, otherwise the object that contained the binding for the name.

#### **Semantics**

2

extensible, and allowing dynamic properties to shadow static properties would make programs harder to understand, and it would make them slower, as it would be hard to perform early binding.)

- The second complication appears with the need for disambiguation. When an unqualified name is resolved the resolution is performed in the context of the namespaces that were open at the point of reference. Thus the search of any one object may find multiple bindings that match the name, up to one binding per open namespace. Instead of making this an error, the name resolver disambiguates by trying to select the most desirable of those namespaces. Selection is performed by filtering the applicable namespaces until we are left with one. (If we have more than one then the name is deemed ambiguous.)
- We first select those namespaces among the matching namespaces that are in use by the least specific class of the object that contains the name. For example, if C is a subclass of B and B is a subclass of A and our name n matched ns1::n, ns2::n and ns3::n and ns3::n was defined in C, then we'd be left with just ns2 and ns2::n was defined in C.
- We then filter by namespace priority. The open namespaces are organized in a prioritized list of namespace sets. If one of the matching names has a namespace that is from a set with a higher priority than all the other matching names, then that's the namespace we want. So if the referencing context of **n** opened **ns2** in a scope nested inside the one that opened **ns1**, then we are left with just **ns2** -- and a single binding, **ns2::n**.
- 7 (The motivation for disambiguation is simple: disambiguation allows more programs to run. Furthermore, since the priority or namespaces during disambiguation is under the control of the programmer, the programmer can rely on disambiguation to control which names that are found.)
- The third complication is that some names are required to be resolved successfully at definition time -- names that denote namespaces and types. (We require that in order to make names and types constant, which generally simplifies the language and makes programs more easily comprehensible.) The consequence of that is that namespace and type references are illegal inside scopes introduced by with or scopes that may be extended by the eval operator, because those scopes make definition time resolution impossible -- their contents are unknown. Such programs result in a syntax error being signalled. (It is possible to ease that restriction in various ways but we have not done so.)
- However, we also require that type and namespace names that are resolved at definition time must resolve to the same bindings that they would resolve to if they were to be resolved at evaluation time. (We require that because it simplifies the user's model of the language: equal names in the same scope have the same meaning, provided they resolve at all.) The consequence of that is that the language must provide protection against ambiguities that can be introduced at a later time. If a name is resolved at definition time to a global binding then compilation units loaded later may introduce new global bindings that will make the resolved binding ambiguous. For example, consider the following program.

```
namespace NS1
namespace NS2
NS1 type T
use namespace NS1, namespace NS2
... var x: T
```

10 The reference to T in the type annotation is resolved uniquely at definition time to NS1::T. Then another compilation unit is loaded:

```
NS2 type T
```

- 11 Since the global environment is "flat"--code in earlier compilation units see bindings introduced by later compilation units--the reference to T from the first program is now ambiguous.
- 12 ES4 protects against this eventuality by *reserving* global names that are resolved at definition time. When T is resolved in the first program and found to be in NS1, the name NS2::T is reserved: it is made off-limits to later programs. As a consequence, the second program above would not be loaded, because the introduction of NS2::T would be an error.
- Names are reserved in namespaces at the same or higher priority level as the namespace that the name was resolved to, so in the example above neither public::T nor internal::T would become reserved, as those namespaces are at lower priority levels than NS1 and NS2.

```
and resolveQualifiedLexicalReference (regs
                                                     : REGS)
                                                    : IDENTIFIER)
                                      (identifier
                                      (namespaceExpr : NAMESPACE EXPRESSION)
    : (OBJECT * NAME) =
    let
        val {scope, global, ...} = regs
        val namespace = evalNamespaceExpr regs namespaceExpr
        val result = searchScopeChain (regs, SOME scope, identifier, [namespace])
    in
        case result of
            NONE
            => (global, {ns=publicNS, id=identifier})
           SOME (object, namespaces)
            => (object, {ns=namespace, id=identifier})
    end
```

# 4.4.3.2 Unqualified Lexical References

1 To resolve an unqualified lexical reference we make use of the full algorithm outlined above, finding the first object that maches the unqualified name in all open namespaces and then disambiguating the set of resulting namespaces.

#### **Semantics**

```
and resolveUnqualifiedLexicalReference (regs
                                                            : REGS)
                                           (identifier
                                                           : IDENTIFIER)
                                           (openNamespaces : OPEN NAMESPACES)
    : (OBJECT * NAME) =
        val {scope, global, ...} = regs
val namespaces = List.concat openNamespaces
         val result = searchScopeChain (regs, SOME scope, identifier, namespaces)
    in
         case result of
             NONE
             => (global, {ns=publicNS, id=identifier})
           | SOME (object, namespaces)
             => let
                     val classFixtureMaps = [getFixtureMap regs object]
                     val result = Fixture.selectNamespaces (identifier,
                                                               namespaces.
                                                               classFixtureMaps,
                                                               openNamespaces)
                    case result of
                         [namespace]
                         => (object, {ns=namespace, id=identifier})
                         => error regs ["ambiguous reference"]
                end
```

### 4.4.3.3 Resolve on a Scope Chain

1 To find an object matching an identifier and a set of namespaces in a scope chain. [CHANGE] remove second lookup pass

#### **Semantics**

2 and searchScopeChain (regs, NONE, ) = NONE

NOTE Top-level "use namespace" pragmas are given a higher priority level than names originating "outside" the compilation unit, as is the case for public and internal.

# 4.7.2 Definition-Time Resolution of Namespace and Type Expressions

- The definition time scope chain is modelled as a list of RIB data structures, defined elsewhere. A rib maps names to fixture bindings that result from defining and binding forms (var, function, type, class, interface, namespace, and others) Ribs have no dynamic properties.
- Definition time resolution resolves name expressions that denote namespaces and types, and performs reservation of global names if necessary.
- Fig. 1. The following algorithm resolves a name expression to a specific name and fixture in the list of ribs:

#### Semantics

4 and resolveNameExpr (ribs : Ast.RIBS)

                              REGS
                             : SCOPE
                 scope
                 namespaces : NAMESPACE SET,
                 identifier : IDENTIFIER)
   : (OBJECT * NAMESPACE_SET) option = let
        val (object, kind) = getScopeObjectAndKind (scope)
    in
        case kind of
                                                     (* FIXME EvalScope is unused *)
            (WithScope
                         EvalScope | GlobalScope)
            => searchObject (regs. SOME object. NONE, identifier, namespaces, false)
            (InstanceScope class)
            => searchObject (regs
                                   SOME object, SOME class, identifier, namespaces, true)
            => searchObject (regs, SOME object, NONE, identifier, namespaces, true)
    end
```

# 4.4.4 Evaluation-Time Resolution of Object References

- Object references are resolved along the prototype chain of the object. Both fixed and dynamic properties are searched in each object, in a single pass over the prototype chain.
- 2 ObjectIndexReference expressions represent computed lookup. The index expression is computed; if it evaluates to a **Name** object then it is used as is, otherwise the value is converted to **string** and qualified with the **public** namespace.

FIXME The following algorithm does not yet handle Name objects

```
Semantics
```

```
and resolveObjectReference (regs:REGS)
                               (ObjectNameReference { object, name, ... }: EXPRESSION)
      (OBJECT option * (OBJECT * NAME)) =
         val obj = evalObjectExpr regs object
    in
         case name of
             UnqualifiedName { identifier, openNamespaces, ... }
=> (SOME obj, resolveUnqualifiedObjectReference regs obj identifier
                                                                    openNamespaces)
             QualifiedName { namespace, identifier }
                             resolveOualifiedObjectReference regs obj identifier
                                                                  namespace)
    end
  | resolveObjectReference regs
                               (ObjectIndexReference {object, index, ...}) =
    let
         val obj = evalObjectExpr regs object
         val idx = evalExpr regs index
val identifier = toUstring regs idx
         (* FIXME if its an Name, then don't convert *)
         val namespace = Namespace publicNS
    in
         (SOME obj. resolveOualifiedObjectReference regs obj identifier namespace)
    end
```

#### 4.4.4.1 Qualified Object References

- 1 Here we describe how an identifier and a namespace expression is resolved to a name of a binding on a specific object.
- 2 To resolve a qualified object reference we evaluate its namespace expression (it must yield a namespace value) and then simply return the object value and the evaluated name.

→ (ribs', name, getFinture (hd ribs') (Ast.PropName name))

## 4.7.2.2 Unqualified Name Expressions

4 An unqualified name expression is resolved according to the full algorithm outlined above. It returns the tail of the list of ribs such that the first rib on the tail contains a binding for the name.

#### **Semantics**

```
and resolveUnqualifiedName (ribs
                                            · Act DIRC
                            (identifier
                                           : IDENTIFIER)
                            (openNamespaces : OPEN_NAMESPACES)
    : (Ast. RIBS * NAME) option =

4.7.2.3 Reserving Names

resolveOnObject regs object identifier namespaces openNamespaces end

## 4.4.4.2 Unqualified Object References

To resolve an unqualified object reference we make use of the full algorithm outlined above, finding the first object that maches the unqualified name in all open namespaces and then disambiguating the set of resulting namespaces.

#### Semantics

### 4.4.4.3 Resolve Name on an Object

#### **Semantics**

```
and resolveOnObject
                    (reas:REGS)
                    (object:OBJECT)
                    (identifier:IDENTIFIER)
                    (namespaces:NAMESPACE SET)
                    (openNamespaces: OPEN NAMESPACES)
      (OBJECT * NAME) =
    let
                   = searchObject (regs. SOME object. NONE. identifier,
                                    namespaces, false)
    in
        case result of
            NONE => (object, {ns=publicNS, id=identifier})
           SOME (object, namespaces) =>
            selectNamespacesByInstanceFixtureMaps regs object identifier
                                                   namespaces openNamespaces
    end
```

# 4.4.5 Common Name Resolution Algorithms

1 The following algorithms are common to the preceding resolver algorithms.

# 4.4.5.1 Single Object Search

Given an object, an identifier and a set of namespaces, this algorithm searches for a matching property name in the object and the object's prototype chain.

```
fun searchObject ( . NONE.
                                : REGS,
: OBJECT option
  | searchObject (regs
                   SOME object
                                : Ast.CLASS option.
                   class
                   identifier
                                : IDENTIFIER,
                               : NAMESPACE SET,
                   namespaces
                   fixedOnly
                                : bool)
    : (OBJECT * NAMESPACE SET) option =
    let
        val matches = getBindingNamespaces (regs.
                                               object
                                               class
                                               identifier,
                                               namespaces,
                                               fixedOnly)
    in
        case matches of
            => if fixedOnly then
                    NONE
                else
                    searchObject (regs.
                                   getPrototypeObject (object),
```

- Statically resolved names must keep their meaning at runtime and therefore cannot be shadowed or be made ambiguous by the later introduction of names. Therefore we reserve the set of names that would cause such conflicts at runtime.
- Given a name and a list of sets of open namespaces, the following algorithm computes a set of names consisting of the identifier and each of the open namespaces with an equal or higher priority than the given namespace.

#### **Semantics**

```
and reserveNames (name)
(openNamespaces)
```

# 4.7.3 Evaluation-time Resolution of Lexical References

- The evaluation time scope chain is modelled as a list of arbitrary objects. A scope object maps names to properties (both fixtures and dynamic properties). Apart from scope objects introduced by the with statement, the evaluation time scope chain mirrors the definition time scope chain.
- The following algorithm resolves a name expression to an object and the name of a property on that object.

#### **Semantics**

# 4.7.3.1 Qualified Lexical References

To resolve a qualified lexical reference we evaluate its namespace expression (it must yield a namespace value) and then look up the name comprised of the namespace value and the qualified reference's identifier. If a binding is not found then we return the global object, otherwise the object that contained the binding.

#### **Cemantics**

#### 4.7.3.2 Unqualified Lexical References

```
NONE, identifier, namespaces, fixedOnly)

=> SOME (object, matches)
end
```

### 4.4.5.2 Disambiguation by Filtering

☐ Given an identifier, a list of namespaces, a list of classes, a list of open namespaces, the following algorithm coordinates the filtering of the set of namespaces: according to the order that the namespaces appear in bindings in the given classes first, and in the priority given by the list of open namespaces second.

#### Semantics

```
: IDENTIFIER,
fun selectNamespaces (identifier
                                       : NAMESPACE SET,
                       namespaces
                                                Ast.FIXTURE MAPS
                       instanceFixtureMaps
                       openNamespaces : OPEN NAMESPACES)
    : NAMESPACE SET =
    let
        val openNamespaceSet = List.concat (openNamespaces)
    in
        case namespaces of
              :: []
            => namespaces
            \overline{	exttt{l}}et
                 val matches' =
                     selectNamespacesByClass (instanceFixtureMaps,
                                                openNamespaceSet,
                                                identifier)
            in
                 case matches' of
                     => raise (LogErr.NameError "internal error")
                     [_]
                     => matches'
                       =>
                     let
                         val matches' =
                              selectNamespacesByOpenNamespaces (openNamespaces,
                                                                  namespaces)
                     in
                         case matches' of
                              []
=> raise (LogErr.NameError "internal error")
                             => matches'
                     end
            end
```

# 4.4.5.2.3 Class Base Namespace Filtering

- Given a list of classes, an identifier and a set of namespaces, the following algorithm selects the namespaces used on the most generic class of that list. This step is necessary to avoid object integrity issues that arise when a derived class introduces a binding with the same identifier and a different namespace in the open namespaces.
- Informal description: Search a class for any instance fixture name bindings that are named by the provided identifier and any of the namespaces in the provided set. Collect the set of matching namespaces used in all such bindings. If the set of matching namespaces is nonempty, return it. Otherwise repeat the process on the next instance fixture map. If all the classes in the list are searched and no matching namespaces are found, return the empty set.

```
Semantics
```

To resolve an unqualified lexical reference we make use of the full algorithm outlined above, finding the first object that maches the unqualified name in all open namespaces and then disambiguating the set of resulting namespaces.

### **Semantics**

```
and resolveUnqualifiedLexicalReference (regs
                                                         : REGS)
                                        (identifier
                                                       : IDENTIFIER)
                                        (openNamespaces : OPEN_NAMESPACES)
    : (OBJ * NAME) =
    let
        val {scope, global, ...} = regs
        val namespaces = List.concat openNamespaces
        val result = searchScopeChain (SOME scope, identifier, namespaces)
    in
        case result of
            NONE
            => (global, {ns=publicNS, id=identifier})
          | SOME (object, namespaces)
            => let
                   val classRibs = instanceRibsOf (object)
                   val result = Fixture.selectNamespaces (identifier,
                                                            namespaces,
                                                            classRibs,
                                                            openNamespaces)
               in
                   case result of
                        [namespace]
                        => (object, {ns=namespace, id=identifier})
                        => error regs ["ambiguous reference"]
               end
    end
```

# 4.7.3.3 Searching a Scope Chain

To find an object matching an identifier and a set of namespaces in a scope chain, first make a pass over the scope chain looking only at fixed properties (except where the scope object is introduced by with or is subject to modification by the eval operator), and if none are found, make a second pass looking also for dynamic properties.

```
identifier
                                     : IDENTIFIER)
: NAMESPACE list =
let
    val fixtureMap = hd instanceFixtureMaps
    val bindingNamespaces =
        getInstanceBindingNamespaces (fixtureMap, identifier, namespaces)
    val matches =
        intersectNamespaces (bindingNamespaces, namespaces)
in
    case matches of
        []
=> selectNamespacesByClass (tl instanceFixtureMaps,
                                     namespaces,
                                     identifier)
          matches
end
```

#### 4.4.5.2.4 Open Namespace Based Namespace Filtering

- Given a list of sets of open namespaces (ordered from most recently opened to least recently opened) and a set of matching namespaces, this algorithm returns a subset of the matching set that occurs entirely within a single open namespace set.
- 2 **Informal description**: intersect the head of the provided open namespace list with the provided set of namespaces. If that intersection is nonempty, return it. Otherwise repeat the process with the tail of the open namespace list. If the end of the list of open namespace sets is reached without producing a nonempty intersection, return an empty set.

```
OBJECT * NAMESPACE_SET) option
         natches = searchScope
          cope { parent, ... } = scope
in
          matches
             +scope
                         : SCOPE,
              namespaces : NAMESPACE SET,
              identifier : IDENTIFIER,
              fixedOnly

    → (OBJECT * NAMESPACE_SET) option =
let
    val (object, kind) = getScopeObjectAndKind (scope)
in
    case (kind, fixedOnly) of
           gearghObject
           NONE
```

## 4.7.4 Evaluation-Time Resolution of Object References

- Object references are resolved along the prototype chain of the object. Both fixed and dynamic properties are searched in each object, in a single pass over the prototype chain.
- DbjectIndexReference expressions represent computed lookup. The index expression is computed; if it evaluates to a Name object then it is used as is, otherwise the value is converted to string and qualified with the public namespace.

FIXME The following algorithm does not yet handle Namo objects.

## 4.7.4.1 Qualified Object References

- Here we describe how an identifier and a namespace expression is resolved to a name of a binding on a specfic object.
- To resolve a qualified object reference we evaluate its namespace expression (it must yield a namespace value) and then simply return the object value and the evaluated name.

### **Semantics**

## 4.7.4.2 Unqualified Object References

To resolve an unqualified object reference we make use of the full algorithm outlined above, finding the first object that maches the unqualified name in all open namespaces and then disambiguating the set of resulting namespaces.

```
+ namespace ··· ()

-> (ebject, {ns-namespace, id-identifier})

+ =

-> error regs ["ambiguous reference"]

end

end
```

# 4.7.5 Common Algorithms

† The following algorithms are common to the preceding resolver algorithms.

## 4.7.5.1 Single Object Search

• Given an object, an identifier and a set of namespaces, this algorithm searches for a matching property name in the object and the object's prototype chain.

#### **Semantics**

```
fun searchObject (NONE, _, _, _) = NONE
  searchObject (SOME object : OBJECT option,
                  identifier : IDENTIFIER,
                  namespaces : NAMESPACE_SET,
                  fixedOnly : bool)
    : (OBJECT * NAMESPACE_SET) option =
    let
        val matches = getBindingNamespaces (ebject,
                                             identifier,
                                             namespaces,
                                             fixedOnly)
    in
        case matches of
            [ ]
            => if fixedOnly then
                   NONE
               else
                   searchObject (getPrototypeObject (object)
                                  identifier,
                                  namespaces,
                                  fixedOnly)
            => SOME (object, matches)
    end
```

### 4.7.5.2 Disambiguation by Filtering

Given an identifier, a list of namespaces, a list of classes, a list of open namespaces, the following algorithm coordinates the filtering of the set of namespaces: according to the order that the namespaces appear in bindings in the given classes first, and in the priority given by the list of open namespaces second.

```
_ =>
        let
            val matches' =
                selectNamespacesByClass (instanceRibs
                                          openNamespaceSet,
                                          identifier)
        in
            case matches' of
                => raise (LogErr.NameError "internal error")
              [_]
                => matches'
              _ =>
                let
                    val matches'' =
                        selectNamespacesByOpenNamespaces (openNamespaces,
                                                           namespaces)

## 4.7.5.2.1 Class Base Namespace Filtering

- Given a list of classes, an identifier and a set of namespaces, the following algorithm selects the namespaces used on the most generic class of that list. This step is necessary to avoid object integrity issues that arise when a derived class introduces a binding with the same identifier and a different namespace in the open namespaces.
- Informal description: Search a class for any instance fixture name bindings that are named by the provided identifier and any of the namespaces in the provided set. Collect the set of matching namespaces used in all such bindings. If the set of matching namespaces is nonempty, return it. Otherwise repeat the process on the next instance rib. If all the classes in the list are searched and no matching namespaces are found, return the empty set.

### 4.7.5.2.2 Open Namespace Based Namespace Filtering

- Given a list of sets of open namespaces (ordered from most recently opened to least recently opened) and a set of matching namespaces, this algorithm returns a subset of the matching set that occurs entirely within a single open namespace set.
- Informal description: intersect the head of the provided open namespace list with the provided set of namespaces. If that intersection is nonempty, return it. Otherwise repeat the process with the tail of the open namespace list. If the end of the list of open namespace sets is reached without producing a nonempty intersection, return an empty set.
